Alternative methods of anesthesia include ice and topical vapor coolants. A sterile drape may be placed over the prepped skin and a bag of ice water placed over the drape. Remove the ice water bag and drape after 5 minutes and perform the procedure. Ethinyl chloride topical vapor coolant may be used as an anesthetic. Spray the solution onto the area of skin in which the needle will be inserted. Apply the spray from 6 inches above the skin. Spray until the skin turns white and frosty. This usually takes 5 to 10 seconds. Immediately perform the procedure, as the anesthesia lasts only 30 to 60 seconds.

TECHNIQUES

THE BASIC TECHNIQUE

The general procedure preferred by one of the authors and the editor (E.F.R.) will be described. Some may prefer to insert the needle

into the joint space and then attach the syringe. Specifics will be addressed with each individual joint.

Apply the needle to the syringe and break the resistance. This avoids any sudden and painful movements of the needle within the joint cavity. Stretch the skin over the site where the needle will be inserted. Penetrate the skin briskly with the needle and enter the joint cavity. Gently aspirate synovial fluid. If bone is encountered, slightly withdraw the needle and readvance it in a different direction. If no fluid is obtained, reevaluate the joint to determine if an effusion is present, if another site is more appropriate for the procedure, or if another physician may offer a different perspective. For diagnostic aspirations, it is not necessary to aspirate all of the fluid from the joint. Synovial fluid analysis can be performed on 1 to 5 mL of fluid.

If additional fluid is to be removed after the original syringe is filled, or if pharmaceuticals are to be injected into the joint, do not remove the needle from the joint cavity. Grasp the hub of the needle with a hemostat. Remove the syringe and attach the second syringe. Continue to aspirate fluid or inject the desired pharmaceutical. Remove the needle when the procedure has been completed. Apply a bandage to the skin. Transfer the synovial fluid into appropriately labeled tubes or containers. Document the procedure in the medical record. A sample procedure note is described below:

After informed consent, the skin overlying the _____ joint was cleaned and prepped with povidone iodine/chlorhexidine solution. The skin was anesthetized with (_____ mL of _____% lidocaine, ethyl chloride vapor coolant, ice for _____ minutes). Using sterile technique, a(n) _____ gauge needle was inserted on the (supero-/infero-, medial/lateral/inferior/superior) surface of the joint. It was directed (supero-/infero-, medially/laterally/inferiorly/superiorly). _____ mL of fluid was obtained. It was (thin, thick, yellow, clear, straw-colored, bloody, purulent, with debris, without debris). No complications were noted.

The joint was injected with _____ mL of _____% (name of local anesthetic) and/or _____ mL of _____% _____ (name of corticosteroid). No complications were noted.

THE BASIC ULTRASOUND TECHNIQUE

The acoustic windows used for US-guided arthrocentesis are the soft tissues overlying the joint. The transducer is most commonly oriented across a joint so that the bones on each side of the joint and the joint space between them are visualized.⁴² Bone is highly reflective of US waves. The cortex is seen as a bright white echogenic line on the US image. Synovial fluid will be seen as an anechoic line or hypoechoic collection within the joint space. When visualized in-plane, the needle will appear as a narrow, linear hyperechoic structure with a posterior reverberation artifact (**Figure 97-1**). When visualized out-of-plane, the needle appears as a small hyperechoic round object.¹²

The general procedure and technique depend on whether the static or dynamic method is used.⁴² For the static technique, manipulate the US transducer over the joint until the optimal spot for needle entry is found based on fluid accessibility and a needle path that avoids major blood vessels, nerves, and tendons. Mark the skin on the midpoint of each side of the US transducer. Rotate the transducer 90° and repeat the process. Connect the two sets of lines to form an "X" that marks the spot for needle entry (**Figure 97-2**). Set aside the US transducer, prepare the skin in a sterile manner, and proceed with the arthrocentesis using the standard landmark-based technique.

The dynamic or real-time method is slightly more demanding technically but offers the advantage of allowing visualization of the

FIGURE 97-1. In-plane view of a needle approaching a joint effusion.

needle and needle tip.¹¹ Prepare the patient's skin in a sterile manner. Place a sterile transducer cover over the US transducer and apply sterile US gel to the skin. Place the transducer over the joint in the appropriate orientation and manipulate it until the synovial fluid is visualized. Inject a local anesthetic agent into the skin and

FIGURE 97-2. The "X" marks the spot for needle entry.

subcutaneous tissue along the projected course of the arthrocentesis needle. In many cases, it is possible to observe the infusion of the anesthetic agent on the US image.¹¹ Advance the needle through the skin and soft tissue and direct it toward the synovial fluid. The needle can be advanced either in-plane or out-of-plane with regard to the US beam. The in-plane orientation allows visualization of the entire needle along its path and is the technique used by most EPs. Visualization in the out-of-plane orientation allows only one cross-sectional area of the needle to be seen, so it can be difficult to identify the needle and its tip. Regardless of orientation, continue to advance the needle until its tip is visible within the synovial fluid. Aspirate the synovial fluid. It is often possible to watch the synovial fluid diminish in size as it is aspirated.

TEMPOROMANDIBULAR JOINT (TMJ) ARTHROCENTESIS

Landmarks: The landmarks for TMJ arthrocentesis are found by first drawing a line on the patient's face from the corner of the eye to the ipsilateral tragus (canthal-tragus line). Mark the point 10 mm from the tragus along the line and 0.5 mm below the line. This marks the posterior border of the superior compartment. Mark a second point 20 mm from the tragus along the line and 1 mm below the line. This marks the anterior border of the superior compartment.

Patient positioning: Place the patient sitting upright with their jaw held slightly open.

Needle insertion and direction: Use two 21 gauge needles to access the joint space compartments. Insert the first needle at the first mark and advance it into the joint space. Inject 2 to 3 mL of sterile saline to insufflate the joint space. Insert and advance the second needle at the second point and into the joint space. Correct placement is confirmed when the saline flows out of the needle.⁴³

US-guided arthrocentesis: With the patient positioned as above, place the US transducer inferior and lateral to the TMJ. Verify the hypoechoic space of the TMJ. The remainder of the technique is described above.

Remarks: Arthrocentesis of this joint is a unique solution to a specialized TMJ disorder called closed lock, in which the patient's jaw is felt to be locked and will not open greater than 20 to 25 mm. It is theorized to be the result of small adhesions and nongliding of the intraarticular disk in the TMJ space. Arthrocentesis and subsequent lavage can relieve the symptoms of closed lock. This is rarely performed by the EP. It is usually performed by Dentists and Oral Surgeons. The technique is easier if a double-needle-single-cannula is used.⁴⁴

Joint injection: Once the two needles are in place in the superior compartment, massive lavage with normal saline or lactated Ringer's solution can be achieved with the first needle as input and the second needle as output. Continuous fluid can be infused and removed using a 10 mL syringe or attaching intravenous (IV) tubing to each needle.⁴⁵

STERNOCLAVICULAR JOINT ARTHROCENTESIS

Landmarks: The sternal end of the clavicle and the suprasternal notch are the landmarks for this joint (Figure 97-3). The joint can be palpated just medial to the sternal end of the clavicle and just lateral to the suprasternal notch.

Patient positioning: Place the patient supine on a stretcher with their arm hanging over the edge of the table (Figure 97-3A). Abduct the arm 90°. Externally rotate the arm so that the palm faces upward. This position maximally opens the sternoclavicular joint to allow easy access.

A

B

FIGURE 97-3. Sternoclavicular joint arthrocentesis. **A.** Patient positioning. **B.** Anatomy and needle insertion. The site of needle insertion is represented by an X.

Needle insertion and direction: Insert a 23 gauge needle through the anterior joint surface and perpendicular to the skin (**Figure 97-3B**). Advance the needle to a depth of 2 to 5 mm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the joint. Verify the hypoechoic and small space of the joint. The remainder of the technique is described above.

Remarks: This joint is often involved with degenerative arthritis. Septic arthritis is commonly seen in IV drug abusers who inject drugs into the great vessels, also known as “pocket shooting.” This can also be seen as a spontaneous infection.⁴⁶ This joint may only contain 0.25 to 0.50 mL of fluid.

Joint injection: A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

ACROMIOCLAVICULAR JOINT ARTHROCENTESIS

Landmarks: The acromioclavicular (AC) joint is very superficial (**Figure 97-4**). Palpate the clavicle and move laterally until a prominence is felt. This is the AC joint. Have the patient move their arm to confirm the joint location.

FIGURE 97-4. Acromioclavicular joint arthrocentesis.

Patient positioning: Place the patient sitting upright on a stretcher with the affected arm hanging by their side. A weight may be placed in the patient’s hand to distract and open the joint space.

Needle insertion and direction: Insert a 22 gauge needle through the superior surface of the AC joint and perpendicular to the skin (**Figure 97-4**). Advance the needle to a depth of 3 to 5 mm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the joint. Verify the hypoechoic and small space of the joint. The remainder of the technique is described above.

Remarks: The AC joint is very superficial. It has a dense, thick capsule anteriorly that is lacking on its superior surface. The joint may contain only 0.25 to 0.50 mL of fluid. US increases the accuracy of joint aspiration.⁴⁷

Joint injection: A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

GLENOHUMERAL JOINT (SHOULDER) ARTHROCENTESIS, ANTERIOR APPROACH

Landmarks: Palpate the coracoid process of the scapula (**Figure 97-5**). It will be found below the lateral third of the clavicle. Internally rotate and adduct the humerus. Palpate the groove between the coracoid process and the humeral head. This groove is the landmark for introduction of the needle.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Flex the elbow 90°. Internally rotate and adduct the arm. In the proper position, the forearm is resting against the patient’s abdomen.

Needle insertion and direction: Insert an 18 gauge needle perpendicular to the skin and into the groove just lateral to the coracoid process (**Figure 97-5B**). Aim the needle directly posterior. Advance the needle until a loss of resistance is felt as the joint cavity is entered.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer inferior and lateral to the coracoid process. Rotate the transducer so that the marker is cephalad and angled

FIGURE 97-5. Shoulder joint arthrocentesis. **A.** Lateral approach. **B.** Anterior approach. The site of needle insertion is represented by an ⊗.

medially toward the patient's head. The curve of the humeral head will appear different from the flat portion of the glenoid. Between these hyperechoic surfaces lies the V-shaped hypoechoic joint space.

Remarks: This approach is the simplest yet most painful of the three approaches. The needle must penetrate the tendons of the coracobrachialis, subscapularis, biceps, and pectoralis major muscles in addition to the very tough anterior joint capsule. The major disadvantage of this approach is the possible, but rare, penetration of the brachial plexus or the axillary vessels with the needle. The patient can watch the large needle as it approaches the skin and this may increase their anxiety level. The posterior approach is preferred when using US guidance.¹² US increases the accuracy of joint aspiration.⁴⁸

Joint injection: A maximum volume of 15 mL may be instilled into this joint. A maximum dose of 30 mg of corticosteroids may be instilled into this joint.

GLENOHUMERAL JOINT (SHOULDER) ARTHROCENTESIS, LATERAL APPROACH

Landmarks: Identify the acromion process of the scapula (Figure 97-5). A groove can be found just inferior to the lateral surface of the acromion and above the greater tubercle of the humerus.

Patient positioning: Place the patient sitting upright on a stretcher with the affected arm hanging by their side. A weight may be placed in the patient's hand to distract and open the joint cavity.

Needle insertion and direction: Insert an 18 gauge needle into the midpoint of the groove (Figure 97-5A). Direct the needle medially and slightly posterior. Advance the needle to a depth of 2.5 to 3 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer under the acromion coracoid process. Identify the joint space. The remainder of the technique is described above.

Remarks: Immediately below the deltoid muscle is the subacromial bursa. This bursa does not communicate with the shoulder joint. The needle must be inserted 2.5 to 3 cm to ensure the needle is in the shoulder joint and not in the subacromial bursa. The anterior

or posterior approach to shoulder arthrocentesis avoids this potential problem.

Joint injection: A maximum volume of 15 mL may be instilled into this joint. A maximum dose of 30 mg of corticosteroids may be instilled into this joint.

GLENOHUMERAL JOINT (SHOULDER) ARTHROCENTESIS, POSTERIOR APPROACH

Landmarks: Identify the spine of the scapula (Figure 97-6). Follow the spine laterally until it turns anterior to become the acromion process. This posterior border of the acromion process is the landmark for this technique. Locate the coracoid process of the scapula, just inferior to the lateral third of the clavicle.

Patient positioning: Place the patient sitting upright on a stretcher. Place the palm of the hand of the affected shoulder on the anterior surface of the opposite shoulder. The arm and forearm should be held against the chest. This position maximally opens the posterior joint space.

Needle insertion and direction: Place the nondominant thumb on the posterior border of the acromion process. Place the nondominant index finger on the coracoid process. Insert an 18 gauge needle 1 to 2 cm below the thumb and parallel to the floor (Figure 97-6). Aim the needle toward the tip of the index finger, approximately 30° medially. Advance the needle to a depth of 2 to 3 cm.

US-guided arthrocentesis: Position the patient as described above. Place the US transducer across the posterior aspect of the shoulder in a transverse orientation (Figure 97-7). The marker may be directed medially or laterally. The echogenic cortex of the humeral head is visible along with the adjacent glenoid rim (Figure 97-8). The joint fluid is visible as an anechoic area between these two bony structures (Figure 97-8). Insert and advance the needle from the lateral edge of the US transducer, oriented along the long axis of the transducer, and into the joint fluid.

Remarks: This is felt by some physicians to be the preferred approach to shoulder arthrocentesis. The needle will pierce the deltoid and infraspinatus muscles and avoid the tendons of the rotator cuff. This approach avoids the anxiety associated with the patient observing the large needle and syringe used for the procedure during the anterior or lateral approach. The posterior joint capsule is much thinner and more easily penetrated than the anterior joint capsule. There are no significant neurovascular structures that may

FIGURE 97-6. Posterior approach for shoulder joint arthrocentesis.

FIGURE 97-7. In the posterior approach to the shoulder, the US transducer is placed in a transverse orientation.

be injured from this approach. US increases the accuracy of joint aspiration.⁴⁸

Joint injection: A maximum volume of 15 mL may be instilled into this joint. A maximum dose of 30 mg of corticosteroids may be instilled into this joint.

FIGURE 97-8. US image of the posterior shoulder. The hypoechoic joint fluid (asterisk) is located between the echogenic cortices of the humeral head (arrow) and the glenoid rim (arrowhead).

HUMERORADIOULNAR JOINT (ELBOW) ARTHROCENTESIS, LATERAL APPROACH

Landmarks: The lateral epicondyle of the humerus, the radial head, and the tip of the olecranon process of the ulna are the landmarks for this joint (**Figure 97-9A**). Flex the elbow 45° and pronate the hand. Pronation of the hand stretches the radial collateral ligament, moves the radial nerve out of the needle's path, and widens the synovial cavity. Identify the depression between the three bony landmarks. The depression is located proximal to the radial head in the area where no bony structures are palpated.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Flex the elbow 45° and pronate the hand. This position widens the joint cavity and avoids any neurovascular structures.

Needle insertion and direction: Insert a 22 gauge needle perpendicular to the skin and into the depression just proximal to the radial head (**Figure 97-9A**). Advance the needle to a depth of 0.75 to 2.0 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US probe at the landmark. Verify the hypoechoic space of the joint. The remainder of the technique is described above.

Remarks: This is the preferred approach for elbow arthrocentesis. It avoids tendons and neurovascular structures, thereby reducing the risk of complications.⁴⁹

Joint injection: A maximum volume of 5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

HUMERORADIOULNAR JOINT (ELBOW) ARTHROCENTESIS, POSTERIOR APPROACH

Landmarks: Identify the top of the olecranon process of the ulna and the triceps muscle insertion into the olecranon process (**Figure 97-9B**). Find the point just proximal to the top of the olecranon and just lateral to the triceps insertion. This point is the landmark for insertion of the needle.

Patient positioning: Place the patient sitting upright on a stretcher. Flex the elbow 90° with the hand supinated. The forearm and hand should be resting on a tabletop or on the patient's ipsilateral leg.

Needle insertion and direction: Approach the joint from the posterolateral surface with the needle parallel to the radial shaft. Insert a 22 gauge needle perpendicular to the skin at the landmark (**Figure 97-9B**). Advance the needle to a depth of 1 cm.

US-guided arthrocentesis: Position the patient as described above. Place the US transducer along the posterior elbow in a longitudinal orientation with the marker toward the shoulder (**Figure 97-10**). This produces an image with the humerus located to the left, the olecranon located to the right, the olecranon fossa at the bottom, and the triceps tendon passing from side to side across the top of the screen (**Figure 97-11**). Keep the US transducer in the same orientation and slide it laterally to move off the triceps tendon. The joint effusion will be visualized in or adjacent to the olecranon fossa (**Figure 97-11**). Be sure to avoid the ulnar nerve, which passes over the medial epicondyle, by choosing a location as far lateral as possible.⁵⁰ Advance the needle over the superior edge of the US transducer and into the synovial fluid.

Remarks: Potential complications include needle penetration of the triceps tendon or the radial nerve. This approach is reserved for patients in whom the lateral approach is contraindicated. US is helpful to guide the procedure.⁵¹

Joint injection: A maximum volume of 5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

FIGURE 97-9. Elbow joint arthrocentesis. The site of needle insertion is represented by an ⊗. **A.** Lateral approach. **B.** Posterior approach. **C.** Posterolateral approach.

HUMERORADIOULNAR JOINT (ELBOW) ARTHROCENTESIS, POSTEROLATERAL APPROACH

Landmarks: Identify the lateral surface of the olecranon process of the ulna and the lateral epicondyle of the humerus (**Figure 97-9C**). Find the indentation just lateral to the olecranon and just distal to the lateral epicondyle. This point is the landmark for the insertion of the needle.

Patient positioning: Place the patient sitting upright on a stretcher. Flex the elbow 90° with the hand supinated. The forearm and hand should be resting on a tabletop or on the patient's ipsilateral leg.

Needle insertion and direction: Approach the joint from the posterolateral surface with the needle parallel to the radial shaft. Insert a 22 gauge needle perpendicular to the skin at the landmark (**Figure 97-9C**). Advance the needle to a depth of 1 cm.

US-guided arthrocentesis: Position the patient as described above. Place the US transducer along the posterior elbow in a longitudinal orientation, with the marker toward the shoulder (**Figure 97-10**). This produces an image with the humerus located to the left, the olecranon located to the right, the olecranon fossa at the bottom, and the triceps tendon passing from side to side across

FIGURE 97-10. The US transducer is placed along the posterior elbow in a longitudinal orientation.

FIGURE 97-11. US image of the longitudinal view of an elbow joint. The hypoechoic joint fluid (asterisk) is located between the echogenic cortices of the humerus (arrow) and the olecranon (arrowhead).

the top of the screen (**Figure 97-11**). Keep the US transducer in the same orientation and slide it laterally to move off the triceps tendon. The joint effusion will be visualized in or adjacent to the olecranon fossa (**Figure 97-11**). Be sure to avoid the ulnar nerve, which passes over the medial epicondyle, by choosing a location as far lateral as possible.⁵⁰ Advance the needle over the superior edge of the US transducer and into the synovial fluid.

Remarks: This approach is an alternative when the lateral approach is contraindicated. US is helpful to guide the procedure.⁵¹

Joint injection: A maximum volume of 5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

RADIOCARPAL JOINT (WRIST) ARTHROCENTESIS

Landmarks: Identify the lunate bone (**Figure 97-12**). Palpate the middle (i.e., third) metacarpal and follow it proximally until a rounded bean-like elevation is felt (**Figure 97-12A**). This is the lunate bone. Palpate the indentations proximal and distal to the lunate bone. The indentation proximal to the lunate bone is the landmark for needle insertion.

Alternatively, identify Lister's tubercle and the extensor pollicis longus (EPL) tendon (**Figure 97-12B**). Lister's tubercle is a bony prominence in the center of the dorsal aspect of the distal radius. The EPL tendon can be found lateral (i.e., radial) to Lister's tubercle. If the EPL tendon is difficult to find, extend the hand and thumb against resistance and it will become prominent. The lunate bone is the bony prominence distal to Lister's tubercle. The indentation proximal to the lunate bone is the landmark for needle insertion.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Pronate the hand with the wrist in slight (20° to 50°) flexion and ulnar deviation (**Figure 97-12A**). The palm of the physician's nondominant hand should be holding the patient's palm. Reidentify the lunate bone with the nondominant thumb.

Needle insertion and direction: Insert a 22 gauge needle perpendicular to the skin in the indentation proximal to the lunate bone (**Figure 97-12A**). Advance the needle to a depth of 0.75 to 1.25 cm.

FIGURE 97-12. Radiocarpal joint arthrocentesis.

Alternatively, insert the needle in the indentation just distal to Lister's tubercle and ulnar to the EPL tendon (**Figure 97-12B**).

US-guided arthrocentesis: With the patient positioned as above, place the US transducer at the indentation proximal to the lunate bone. Verify the hypoechoic and small space of the joint. The remainder of the technique is described above.

Remarks: The preferred, and easiest, method is to identify the lunate bone and then insert the needle in the indentation just proximal to it.

Joint injection: A maximum volume of 2 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

INTERCARPAL JOINT ARTHROCENTESIS

Landmarks: Identify the lunate bone (**Figure 97-12**). Palpate the middle (i.e., third) metacarpal and follow it proximally until a rounded bean-like elevation is felt (**Figure 97-12A**). This is the lunate bone. Palpate an indentation distal to the lunate bone and proximal to the base of the third metacarpal. This indentation is the landmark for insertion of the needle.

FIGURE 97-13. Intercarpal joint arthrocentesis. Coronal section through the wrist and hand demonstrating that the joints between the carpal bones are all interconnected. The site of needle insertion is represented by an X.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Pronate the hand with the wrist in slight (20° to 50°) flexion and ulnar deviation (**Figure 97-12A**). The palm of the physician's nondominant hand should be holding the patient's palm. Reidentify the landmarks with the nondominant thumb.

Needle insertion and direction: Insert a 22 gauge needle perpendicular to the skin in the indentation distal to the lunate bone. Advance the needle to a depth of 0.5 to 1.0 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer at the indentation distal to the lunate bone. Verify the hypoechoic and small space of the joint. The remainder of the technique is described above.

Remarks: The joints between the carpal bones are all connected to each other (**Figure 97-13**). Fluid aspirated from one of these joints is representative of all the joints. Likewise, injection of one joint allows the pharmaceutical to be distributed to all the joints.

Joint injection: A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 15 mg of corticosteroids may be instilled into this joint.

CARPOMETACARPAL JOINT OF THE THUMB ARTHROCENTESIS

Landmarks: The base of the first metacarpal and the abductor pollicis longus (APL) tendon are the landmarks for this joint (**Figure 97-14**). Identify the radial aspect of the base of the first metacarpal. Have the patient rotate the affected thumb to help identify the joint. Identify the APL tendon by extending the patient's thumb against resistance.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Flex the thumb into the palm with the tip of the thumb touching the fifth metacarpal head. Clench the remaining fingers into a fist (**Figure 97-14A**).

FIGURE 97-14. Carpometacarpal joint of the thumb arthrocentesis. **A.** Recommended approach. The dotted line represents the proper direction for needle insertion, toward the base of the fourth metacarpal. **B.** An alternative technique. The arrow represents the application of distal traction.

Needle insertion and direction: Insert a 22 gauge needle into the joint space at the radial aspect of the base of the first metacarpal and just lateral (i.e., radial) to the APL tendon (**Figure 97-14A**). Direct the tip of the needle toward the base of the fourth metacarpal. Advance the needle to a depth of 0.5 to 1.0 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the carpometacarpal joint. Rotate the transducer so that the marker is cephalad and angled medially toward the patient's head. Between the hyperechoic surfaces of the bones lies the small and narrow hypoechoic joint space. The remainder of the technique is described above.

Remarks: If difficulty is encountered when inserting the needle, try an alternative thumb position (**Figure 97-14B**). Flex the first carpometacarpal joint 45° and apply distally directed traction to the distal thumb. This in-line traction will enlarge the joint cavity and allow easier access.

Joint injection: A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

METACARPOPHALANGEAL JOINT OF THE FINGER ARTHROCENTESIS

Landmarks: Identify the metacarpophalangeal (MCP) joint and the extensor digitorum tendon (**Figure 97-15A**). The MCP joint can be located just proximal to the prominence at the base of the proximal phalanx of the finger. Identify the extensor tendon by having the patient extend the finger against resistance.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Pronate the hand and abduct the fingers. Grasp the finger and apply distally directed traction.

Needle insertion and direction: Insert a 22 gauge needle into the dorsal joint space just medial or lateral to the extensor tendon (**Figure 97-15B**). Direct the tip of the needle toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the MCP joint. Rotate the transducer

FIGURE 97-15. Arthrocentesis of the metacarpophalangeal and interphalangeal joints. **A.** Proper needle placement. **B.** Distal traction will cause dimpling of the skin in the areas noted by the ⊗. These areas of skin dimpling are the landmarks for needle insertion. The arrow represents the application of distal traction.

so that the marker is cephalad and angled medially towards the patient's head. Between the hyperechoic surfaces of the bones lies the small and narrow hypoechoic joint space. The remainder of the technique is described above.

Remarks: The application of distal traction often causes a depression to appear on both sides of the extensor tendon (**Figure 97-15B**). These depressions can be used as landmarks for the site of needle insertion into the joint cavity.

Joint injection: A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 5 mg of corticosteroids may be instilled into this joint.

INTERPHALANGEAL JOINT OF THE FINGER ARTHROCENTESIS

Landmarks: Identify the interphalangeal (IP) joint and the extensor tendon of the fingers (**Figure 97-15A**). The IP joint can be located just proximal to the prominence at the base of the middle or distal phalanx of the finger. Identify the extensor tendon by having the patient extend the finger against resistance.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Pronate the hand and abduct the fingers. Grasp the finger and apply distally applied traction.

Needle insertion and direction: Insert a 22 gauge needle into the dorsal joint space just medial or lateral to the extensor tendon (**Figure 97-15B**). Direct the tip of the needle toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the IP joint. Rotate the transducer so that the marker is cephalad and angled medially towards the patient's head. Between the hyperechoic surfaces of the bones

lies the small and narrow hypoechoic joint space. The remainder of the technique is described above.

Remarks: The application of distal traction often causes a depression to appear on both sides of the extensor tendon (**Figure 97-15B**). These depressions can be used as landmarks for the site of needle insertion into the joint cavity. The joints are small and normally contain almost no synovial fluid. When inflamed or infected, the joint cavity may contain up to 2 mL of synovial fluid.

Joint injection: A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 5 mg of corticosteroids may be instilled into this joint.

HIP JOINT ARTHROCENTESIS, ANTERIOR APPROACH

Landmarks: Identify the anterior superior iliac spine (ASIS) and the femoral pulse (**Figure 97-16**). The landmark for insertion of the needle is 2 to 3 cm below the ASIS and 2 to 3 cm lateral to the femoral artery pulse.

Patient positioning: Place the patient supine on a stretcher with the affected leg internally rotated and the knee slightly flexed.

Needle insertion and direction: Insert a 3.5 inch, 18 gauge needle at the landmark (**Figure 97-16**). Direct the tip of the needle posteromedially. Insert the needle at a 60° angle to the skin of the thigh. Advance the needle until bone is encountered. Slightly withdraw the needle and begin aspirating the synovial fluid.

US-guided arthrocentesis: Position the patient as described above.²⁰ Place the US transducer over the anterior hip and aligned with the long axis of the femoral neck, with the marker in a superior-medial direction and aimed toward the umbilicus (**Figure 97-17**).¹¹ The echogenic cortex of the femoral head is visible to the left of the image and the femoral neck to the right. The concave transition

FIGURE 97-16. Anterior approach for hip joint arthrocentesis. The curved arrow represents internal rotation of the femur.

between these two areas is the anterior synovial recess.^{11,20} Synovial fluid will be seen in this recess and tends to displace the joint capsule anteriorly (**Figure 97-18**).¹¹ Insert the needle from the inferolateral edge of the US transducer and advance it into the synovial fluid.

Remarks: This approach is technically easier and recommended by many authors.⁵² A long spinal needle is usually required for this procedure. Use caution as the needle may injure the articular cartilage. This procedure should be performed by a consultant (e.g., an Orthopedist, a Rheumatologist, or a Radiologist) under fluoroscopic guidance if US is not available in the ED.

Joint injection: A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

FIGURE 97-18. US image of a hip effusion. The hypoechoic effusion (asterisk) is located in the anterior synovial recess between the echogenic cortices of the femoral neck (arrowhead) and the femoral head (arrow).

HIP JOINT ARTHROCENTESIS, LATERAL APPROACH

Landmarks: The greater trochanter is the landmark for this technique (**Figure 97-19**). Place the patient supine with the affected leg internally rotated. Palpate the greater trochanter.

Patient positioning: Place the patient supine on a stretcher with the affected leg internally rotated (**Figure 97-19A**). Identify the greater trochanter and hold it between the thumb and index finger. A second patient position may be used for the alternative approach (**Figure 97-19B**). Place the patient lying on the unaffected side. Flex the unaffected, lower leg 90°. Fully extend the upper, affected, leg with a pillow supporting the ankle.

Needle insertion and direction: Insert a 3.5 inch, 18 gauge needle just superior to the superior margin of the greater trochanter (**Figure 97-19A**). Advance the needle horizontally, parallel to the stretcher, until it contacts the femoral neck. Withdraw the needle 2 to 4 mm and redirect it slightly cephalad. Advance the needle while applying negative pressure to the syringe until synovial fluid enters the syringe. Stop advancing the needle and continue to aspirate the synovial fluid. The alternative technique requires the insertion of the needle perpendicular to the skin and 1 cm proximal to the greater trochanter (**Figure 97-19B**). Advance the needle until the femoral neck is contacted. Withdraw the needle 2 mm and begin aspirating synovial fluid.

Remarks: In the morbidly obese, the greater trochanter may not be palpable. This approach is technically more difficult than the anterior approach. The advantage of this approach is that the articular cartilage will not be in the needle's path and so avoids injury. This procedure should be performed by a consultant (e.g., an Orthopedist, a Rheumatologist, or a Radiologist) under fluoroscopic guidance.

FIGURE 97-17. The US transducer is placed anteriorly over the hip joint and aligned with the long axis of the femoral neck.

FIGURE 97-19. Lateral approach for hip joint arthrocentesis. **A.** The patient is supine with the leg internally rotated (*curved arrow*). A needle is inserted above the greater trochanter and advanced until the femoral neck is encountered (1). The needle has been withdrawn slightly, redirected cephalad, then readvanced into the joint cavity (2). **B.** An alternative approach.

Joint injection: A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, SUPRAPATELLAR APPROACH

Landmarks: Identify the midpoint of the superolateral or superomedial border of the patella (**Figure 97-20A**). Either of these landmarks may be used as the site for needle insertion.

Patient positioning: Place the patient supine on a stretcher with the affected knee fully extended.

Needle insertion and direction: Insert an 18 gauge needle through the midpoint of the superolateral or superomedial border of the patella (**Figure 97-20A**). Direct the tip of the needle toward the intercondylar notch of the femur. Advance the needle to a depth of 1.5 to 3.0 cm.

US-guided arthrocentesis: Position the patient as described above. A small roll or towel can be used behind the knee to provide slight flexion. Place the US transducer in a longitudinal orientation superior to the patella, with the marker directed toward the patient's

head. The cortex of the distal femur is visible as a bright echogenic line to the right of the image and the synovial fluid is visible deep to the quadriceps tendon (**Figure 97-21**). Keep the US transducer oriented longitudinally and slowly slide it medially or laterally to move off the quadriceps tendon. Insert the needle from the superior edge of the US transducer in a longitudinal orientation and direct it toward the synovial fluid. Advance the needle into the synovial fluid.

Remarks: The needle enters the suprapatellar bursa and avoids any potential damage to the articular cartilage. The bursa is a direct continuation of the synovial cavity.¹¹ There are no neurovascular structures of significance to injure with this approach. If the knee effusion is minimal, synovial fluid might not be aspirated from this approach. Approximately 10% to 15% of the population has a plica completely separating the suprapatellar bursa from the knee joint. If this variation exists in the patient, the bursa fluid will not

FIGURE 97-20. Knee joint arthrocentesis. The site of needle insertion is represented by an **X**. **A.** Medial and lateral suprapatellar approach. **B.** Medial and lateral parapatellar approach. **C.** Medial and lateral infrapatellar approach.

FIGURE 97-21. US image of a knee effusion. The hypoechoic joint fluid (*asterisk*) is located above the echogenic cortex of the distal femur (*arrow*).

represent synovial fluid. The use of US has been shown to improve the patient-reported clinical outcomes.⁵³

Joint injection: A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, PARAPATELLAR APPROACH

Landmarks: Identify the midpoint of the lateral or medial border of the patella (**Figure 97-20B**). Either of these landmarks may be used as the site for needle insertion.

Patient positioning: Place the patient supine on a stretcher with the affected knee fully extended.

Needle insertion and direction: Insert an 18 gauge needle just below the midpoint of the lateral or medial border of the patella (**Figure 97-20B**). Direct the needle perpendicular to the long axis of the leg and aimed toward the intercondylar notch of the femur. Advance the needle to a depth of 1 to 2 cm.

US-guided arthrocentesis: Place the US transducer oriented longitudinally, and either lateral or medial to the patella, with the marker directed toward the patient's head. Identify the joint fluid. Slowly rotate the US transducer to a horizontal orientation to identify the area with the largest anechoic fluid collection.¹¹ Insert and advance the needle along the superior edge of the US transducer and into the joint fluid.

Remarks: The easiest site for arthrocentesis is the medial parapatellar region. There are no disadvantages to using the medial parapatellar site.

Joint injection: A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, INFRAPATELLAR APPROACH

Landmarks: Identify the inferior border of the patella and the patellar tendon (**Figure 97-20C**). The tendon is a thick band that passes from the inferior border of the patella to the tibial tuberosity.

Patient positioning: Place the patient sitting upright on a stretcher with the affected knee bent 90° over the edge of the bed and the leg hanging freely and unsupported.

Needle insertion and direction: Insert an 18 gauge needle 0.5 cm below the inferior border of the patella at the level of the joint line and just medial or lateral to the patellar tendon (**Figure 97-20C**). Direct the needle perpendicular to the long axis of the leg and aimed toward the intercondylar notch of the femur. Advance the needle to a depth of 1.5 to 2.0 cm.

Remarks: The weight of the leg helps to open the joint cavity. The risk of injury to the articular cartilage is minimal. This approach was popular in the past but is not often used today. **Do not pierce the patellar tendon with the needle.**

Joint injection: A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

TIBIOTALAR JOINT (ANKLE) ARTHROCENTESIS, ANTEROLATERAL APPROACH

Landmarks: Identify the joint cavity, the lateral malleolus, and the extensor digitorum longus (EDL) tendons (**Figure 97-22**). The joint cavity is located below the distal edge of the fibula and between the bases of the malleoli. Extend the toes against resistance to identify the EDL tendons. Palpate the base of the lateral malleolus.

Patient positioning: Place the patient sitting upright or supine on a stretcher. The patient can also be placed sitting upright on a

stretcher with affected knee bent 90° over the edge of the bed and the foot hanging freely and unsupported. Plantar flex the ankle.

Needle insertion and direction: Insert a 22 gauge needle perpendicular to the fibular shaft at the level of the base of the lateral malleolus; midway between the malleolus and the lateral border of the EDL tendon (**Figure 97-22A**). Advance the needle to a depth of 0.5 to 1.0 cm.

US-guided arthrocentesis: Position the patient as described above. Place the US transducer over the anterior tibiotalar joint in a longitudinal orientation, with the marker of the US transducer toward the patient's head (**Figure 97-23**).^{11,17} Manipulate the US transducer with a slight rotation until the echogenic cortex of the tibia and talus bones are both visible (**Figure 97-24**). The tibia is visible to the left of the image and the talus to the right. During the rotation of the US transducer, note the location of the dorsalis pedis artery and the extensor tendons so that they may be avoided when inserting the needle.¹¹ The joint fluid is visible as a hypoechoic area in the V-shaped recess between the tibia and talus (**Figure 97-24**). Insert the needle at the inferior end of the transducer and advance it into the joint fluid.

Remarks: This approach avoids potential injury to the dorsalis pedis vessels and the deep peroneal nerve.

Joint injection: A maximum volume of 3 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

TIBIOTALAR JOINT (ANKLE) ARTHROCENTESIS, ANTEROMEDIAL APPROACH

Landmarks: Identify the joint cavity, the medial malleolus, and the tendons of the tibialis anterior (TA) and the extensor hallucis longus (EHL) muscles (**Figure 97-22**). The joint cavity is located below the distal edge of the tibia and between the bases of the malleoli. Extend the great toe against resistance to identify the EHL tendon. Plantar flex the ankle against resistance to identify the TA tendon. Palpate the base of the medial malleolus.

Patient positioning: Place the patient sitting upright or supine on a stretcher. The patient can also be placed sitting upright on a stretcher with the affected knee bent 90° over the edge of the bed and the foot hanging freely and unsupported. Plantar flex the ankle to use the EHL tendon as the landmark for the procedure. Alternatively, plantar flex the ankle and invert the subtalar joint to use the TA tendon as the landmark for the procedure.

Needle insertion and direction: Insert a 22 gauge needle perpendicular to the tibial shaft at the level of the base of the malleolus and medial to the EHL tendon (**Figure 97-22B**). Alternatively, insert the needle medial to the TA tendon (**Figure 97-22C**).

US-guided arthrocentesis: The procedure is exactly as described above for the anterolateral approach.

Remarks: If using the EHL tendon as the landmark, use caution to avoid the dorsalis pedis vessels and the deep peroneal nerve that usually lie immediately lateral to the EHL tendon.

Joint injection: A maximum volume of 3 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

SUBTALAR JOINT ARTHROCENTESIS

Landmarks: Identify the tip of the medial malleolus. Palpate the sustentaculum tali of the calcaneus (**Figure 97-25**). It is approximately 1.5 to 2.0 cm below the tip of the medial malleolus.

Patient positioning: Place the patient supine on a stretcher with the foot held at a right angle to the leg. Externally rotate the hip until the medial malleolus is pointing upward.

Needle insertion and direction: Insert a 22 gauge needle immediately above and slightly posterior to the sustentaculum tali (**Figure 97-25**). Advance the needle to a depth of 1.5 to 2.0 cm.

FIGURE 97-22. Arthrocentesis of the ankle joint. The site of needle insertion is represented by an ⊗. **A.** Anterolateral approach. **B.** Anteromedial approach. **C.** An alternative technique for the anteromedial approach.

Remarks: This is a difficult procedure because the joint space is very small. Fluoroscopy may be required to gain entry into the joint cavity. This procedure is seldom performed in the ED. US is not very helpful due to the small joint space and irregular body and bony surfaces.

Joint injection: A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

INTERTARSAL JOINT ARTHROCENTESIS

There are no specific landmarks for the many intertarsal joints. Radiographs are required to identify the location of a specific joint. Plain radiographs are often not helpful and fluoroscopic guidance is usually required. For these reasons, arthrocentesis of these joints is not routinely performed in the ED. Some authors recommend

FIGURE 97-23. The US transducer is placed over the anterior tibiotalar joint in a longitudinal orientation.

probing the general area of the joint with a needle until it enters the joint cavity. This is extremely painful for the patient and risks injury to the articular cartilage. Therefore, this technique cannot be recommended.

METATARSOPHALANGEAL JOINT ARTHROCENTESIS

Landmarks: Identify the metatarsophalangeal (MTP) joint and the extensor tendon. The MTP joint can be located just proximal to the prominence at the base of the proximal phalanx of the toe. Identify the extensor tendon by having the patient extend the toe against resistance.

FIGURE 97-24. US image of the longitudinal view of the anterior tibiotalar joint. The hypoechoic joint fluid (asterisk) is located in the recess between the echogenic cortices of the tibia (arrow) and talus (arrowhead).

FIGURE 97-25. Subtalal joint arthrocentesis.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Plantar flex the foot. Grasp and plantar flex the toe 15° to 20° and apply distal traction (**Figure 97-26A**).

Needle insertion and direction: Insert a 22 gauge needle into the dorsal joint space and just medial or lateral to the extensor tendon (**Figure 97-26B**). Direct the tip of the needle toward the center of the MTP joint. Advance the needle to a depth of 0.3 to 0.5 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the MTP joint. Rotate the transducer so that the marker is cephalad and angled medially towards the patient's head. Between the hyperechoic surfaces of the bones lies the small and narrow hypoechoic joint space. The remainder of the technique is described above.

Remarks: The application of distal traction often causes a depression to appear on both sides of the extensor tendon. These depressions can be used as landmarks for the site of needle insertion into the joint cavity.

Joint injection: A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

INTERPHALANGEAL JOINT OF THE TOE ARTHROCENTESIS

Landmarks: Identify the interphalangeal (IP) joint and the extensor tendon. The IP joint can be located just proximal to the prominence at the base of the middle or distal phalanx of the toe. Identify the extensor tendon by having the patient extend their toes against resistance.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Plantar flex the foot. Grasp and plantar flex the toe 15° to 20° and apply distal traction (**Figure 97-26A**).

Needle insertion and direction: Insert a 23 gauge needle into the dorsal joint space and just medial or lateral to the extensor tendon (**Figure 97-26B**). The needle should be aimed toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm.

US-guided arthrocentesis: With the patient positioned as above, place the US transducer superior to the IP joint. Rotate the transducer so that the marker is cephalad and angled medially toward the patient's head. Between the hyperechoic surfaces of the bones lies the small and narrow hypoechoic joint space. The remainder of the technique is described above.

Remarks: The application of distal traction often causes a depression to appear on both sides of the extensor tendon. These depressions can be used as landmarks for the site of needle insertion into

FIGURE 97-26. Arthrocentesis of the metatarsophalangeal and interphalangeal joints of the foot. **A.** The ankle is plantar flexed. The affected toe is flexed 15° to 20° at the metatarsophalangeal joint and distal traction is applied (arrow). **B.** The needle is inserted just inferomedial or inferolateral to the extensor tendon at the level of the metatarsophalangeal joint (1) or the interphalangeal joint (2).

the joint cavity. These joints are small and normally contain almost no synovial fluid. When inflamed or infected, the joint cavity may contain up to 1.5 mL of synovial fluid.

Joint injection: A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 5 mg of corticosteroids may be instilled into this joint.

JOINT INJECTION TECHNIQUE

A joint may be injected with corticosteroids and/or local anesthetic solution to relieve pain and inflammation. Identify the anatomic landmarks, prepare the patient, and insert the needle as if performing an arthrocentesis. Inject the pharmaceutical(s), remove the needle, and apply a bandage.

Occasionally, synovial fluid may be required for analysis prior to the injection of pharmaceuticals. A prospective randomized study in rheumatoid arthritis patients found that aspirating all the synovial fluid prior to therapeutic steroid injection reduced the risk of relapse, led to better outcomes, and increased symptom relief.⁵⁴ Identify the anatomic landmarks, prepare the patient, and insert the needle as if performing an arthrocentesis. Aspirate the synovial fluid into the syringe. With the needle still in the joint, grasp the hub of the needle with a hemostat. Remove the original syringe containing the aspirated synovial fluid. Attach a second syringe containing the pharmaceutical(s) to be injected into the synovial cavity. Re-aspirate to confirm that the needle tip remained within the synovial cavity. Inject the pharmaceutical(s). While injecting, no resistance should be felt. If resistance is encountered, the needle may have dislodged from the joint cavity. Remove the needle, reinsert it into the synovial cavity, aspirate to confirm proper positioning, and then inject the pharmaceutical(s). After injection, remove the needle and apply a bandage.

ULTRASOUND AND PEDIATRIC HIP EFFUSIONS

Evaluation of a suspected pediatric hip joint effusion requires consideration of septic arthritis versus a toxic synovitis.^{20,55,56} Toxic synovitis is the most common cause of hip pain in children and occurs most frequently between the ages of 3 and 6 years. It is a nonpyogenic, inflammatory condition of the joint synovium with an unknown etiology. It occurs most commonly in the hip joint and occasionally in the knee joint.

In contrast, septic arthritis is an acute pyogenic inflammation that occurs most commonly in children below the age of 4 years, with

a peak incidence between 6 and 24 months of age. Useful studies include serum white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), blood cultures, plain films, computed tomography (CT), magnetic resonance imaging (MRI), and US. The most critical diagnostic information comes from aspiration and analysis of joint fluid.

US has been shown to be as accurate as MRI in detecting effusions. It is most easily performed using an anterior approach with the US transducer oriented in the sagittal plane and parallel to the femoral neck. An effusion is visible as a convex, rather than concave, joint capsule more than 5 mm thick. Transudates are more often hypoechoic, whereas exudates and hemorrhage are usually more hyperechoic.⁵⁷

Many imaging techniques such as plain film, scintigraphy, MRI, and CT are useful in the differentiation of these two clinical entities. MRI and CT provide the highest quality information. However, these studies usually require sedation or even general anesthesia in young children due to the long examination times and the requirement for no motion. US-guided hip joint arthrocentesis is a useful bedside imaging technique to help solve this problem.

US can detect the presence of a joint effusion. It cannot reliably differentiate between toxic synovitis and septic arthritis without joint fluid aspiration and analysis. US should not be used as the primary means of ruling out a suspected septic arthritis.⁵⁶⁻⁵⁸

AFTERCARE

No special care or precautions are required after performing an arthrocentesis. Pain can be relieved with the use of ice, elevation, and nonsteroidal anti-inflammatory drugs. Joint injection, on the other hand, often requires some precautions. Some recommend limiting joint activity for 4 to 8 hours if an anesthetic solution is injected into a joint. An anesthetized joint, especially weight-bearing joints, may be susceptible to further injury when the joint has decreased sensation. Injection of corticosteroids into a joint cavity often requires a period of immobilization. This discussion is beyond the scope of this chapter. The readers should refer to a rheumatology textbook, orthopedic textbook, or the medical literature for this information.

COMPLICATIONS

Complications can occur with joint aspiration and/or injection (Table 97-3). Most of the complications are minor. Significant complications are rare but do occur.

TABLE 97-3 Complications Associated with the Aspiration and/or Injection of Joints

Allergic reactions
Bleeding
Cartilage injury
Dry tap
Infection
Joint instability
Needle-associated complications
Corticosteroid-induced complications
Vasovagal reactions

ALLERGIC REACTIONS

Allergic reactions can occur from hypersensitivity to the local anesthetic solution. Symptoms can range from mild itching and urticaria to circulatory collapse and death. Severe allergic reactions are extremely rare but may occur. Taking a thorough history can prevent many allergic reactions. The preservative in the local anesthetic solution is often the cause of the allergic reaction. Local anesthetic solutions containing no preservatives are an alternative. Some authors believe local anesthesia is not required, as the pain of anesthetic injection is equal to performing the procedure without injectable anesthesia.^{10,41} If one is concerned about a potential allergic reaction associated with local anesthetic solutions, topical ice or vapor coolant is an acceptable alternative to nothing. A solution of 1% or 2% diphenhydramine can also be used as an injectable local anesthetic agent for the skin and soft tissues. Do not inject diphenhydramine into the joint cavity as this can result in significant inflammatory reactions and possible crystal deposition.

CARTILAGE INJURY

The articular cartilage can be damaged from improper needle insertion or needle movement within the joint cavity. The actual incidence of cartilage injury is unknown. The cartilage is avascular and injuries do not heal. Damaged cartilage can lead to focal degenerative changes and be a nidus for future infection. Injury to the articular cartilage can be prevented with a few simple steps. Select a site for the procedure and a needle path that avoids the articular cartilage. Aspirate as you slowly enter the joint cavity and stop inserting the needle when synovial fluid enters the syringe. There is no advantage to plunging the needle into the middle of the joint cavity. Avoid needle movement once the joint cavity has been entered. Finally, do not try to completely aspirate all the fluid within the joint cavity.

DRY TAP

A needle inserted into a joint does not always guarantee fluid will be aspirated.⁵⁹ A dry tap can occur due to improper needle placement, a small or absent effusion, mechanical obstruction, or chronic inflammation.

A dry tap can result from improper needle placement. If the needle is not within the joint cavity, no fluid will be aspirated. Slightly withdraw the needle and reinsert it at a different angle. Alternatively, remove the needle, re-identify the anatomic landmarks, and then reinsert the needle.

One of the most common reasons for a dry tap is the lack of an effusion or a small one. It may be difficult on physical examination to determine if an effusion is present. This is especially true if the patient is obese or if a large amount of subcutaneous edema is present. Try using the non-syringe-bearing hand to “milk” fluid toward the needle while aspirating. Alternatively, if a small effusion is suspected, inject a small amount of sterile saline into the joint cavity.

Allow the saline to remain for 30 to 60 seconds, and then aspirate the fluid.

Synovial fluid may be loculated or inaccessible by the chosen site of needle entry if the joint has been previously injured. Choose an alternate approach or site to enter the joint cavity. This may facilitate synovial fluid aspiration.

Mechanical obstruction can result in a dry tap. Gently move the needle tip to determine if it can move freely. If it doesn't, it may be caught or embedded in cartilage, periosteum, or synovium. Withdraw the needle 1 to 2 mm and re-aspirate. The needle may also be within the intraarticular fat pad. Slightly withdraw the needle and re-aspirate. A plica may be obstructing the lumen of the needle. Rotate the needle and re-aspirate. If no fluid is aspirated, slightly advance the needle and re-aspirate. If still no fluid is obtained, attempt an alternate approach or reconsider whether an effusion is present and whether the procedure is actually required.⁵⁹

The synovial fluid itself may be the cause of a dry tap. The presence of purulent fluid or fluid with debris may clog the needle. Remove the needle and repeat the procedure with a larger gauge needle. If the needle clogs during the aspiration, try reinjecting a small amount of the synovial fluid to dislodge the obstruction and then re-aspirate. A larger gauge needle may be required to complete the procedure.

Aspiration of synovial fluid from a chronically inflamed joint may be problematic. The synovium may undergo fatty replacement known as lipoma arborescens. Long-standing inflammatory fluid may be resorbed, leaving a thick gelatinous material that is difficult to aspirate. In these cases, arthrocentesis should be referred to the experienced clinician or a consultant.

HEMORRHAGE

Significant bleeding is extremely rare. External hemorrhage can be controlled with direct pressure over the puncture site. Hemarthroses are usually small, self-limited, and only require observation. If a significant hemarthrosis or external hemorrhage occurs, treatment may be required to reverse the anticoagulant or replace clotting factors. The readers should refer to another source for management of these complications, as a detailed discussion is beyond the scope of this chapter.

Arthrocentesis can be safely performed in patients who are anticoagulated or have a bleeding disorder. The most experienced EP should perform the procedure to limit any potential complications and bleeding. Also reconsider if the procedure must be done immediately in the ED. The only true indication to perform an arthrocentesis in a coagulopathic patient in the ED is to rule out a septic joint.

INFECTION

Infection of a sterile joint can occur when the needle penetrates unclean skin, cellulitic skin, infected subcutaneous tissues, or skin lesions. If proper aseptic technique is used, the risk of infecting a sterile joint occurs in less than 1:10,000 arthrocenteses.^{10,60} The risk of infection is negligible when the skin is properly cleansed, aseptic technique is used, and the skin is not punctured through an obvious infection or through a skin lesion that may harbor micro-organisms. An added benefit to the use of ethyl chloride topical vapor coolant is that it decreases bacteria on the skin surface.⁶¹

HYPODERMIC NEEDLE-ASSOCIATED COMPLICATIONS

The hypodermic needle can be the source of complications in rare circumstances. The needle may separate from the hub during the procedure and require a minor surgical procedure to recover it.⁶²

The needle tip may be advanced too deep and become embedded in the bony skeleton surrounding the joint. Upon withdrawing the syringe, the needle tip may break off and remain embedded in the bone or the needle may separate from the hub.

CORTICOSTEROID-INDUCED COMPLICATIONS

Corticosteroid-induced complications can be acute or chronic.^{9,10,37,63-67}

The most severe acute complication is injection of corticosteroids into an infected joint. A septic arthritis must be ruled out prior to instillation of corticosteroids into a joint cavity. Other local complications include steroid arthropathy, Charcot arthropathy, osteonecrosis, aseptic necrosis, tissue atrophy, tendon rupture, fat necrosis, formation of calcifications, joint instability, intraneural injection, and postinjection flare. Systemic complications include flushing, pancreatitis, posterior subcapsular cataracts, and hyperglycemia. Due to the potential for complications, many clinicians defer corticosteroid injections to the Orthopedist, Rheumatologist, or Sports Medicine consultant.

VASOVAGAL REACTIONS

The patient may experience an increase in vagal tone from apprehension, needle phobias, and/or pain. Vasovagal reactions are relatively common and may be associated with light-headedness and/or fainting. To prevent secondary injury to the patient, arthrocentesis should be performed with the patient on a stretcher or in a chair that reclines. These vasovagal reactions are self-limited and only require reassurance.

SYNOVIAL FLUID ANALYSIS

Hailed as the most valuable test in rheumatology, synovial fluid analysis provides essential diagnostic information for the appropriate management and treatment of urgent and emergent arthritic conditions.^{6,10,68} It has been established as a fundamental component to the complete and appropriate work-up of arthritic diseases. With the possibility of potential joint destruction and chronic disability, **the role of synovial fluid analysis in the expedient diagnosis and treatment of acute joint disease cannot be overemphasized.**⁶⁹

Controversy exists concerning what constitutes the appropriate guidelines for a “routine” synovial fluid analysis.^{10,70-74} This controversy arises from multiple issues that include the clinical scenario, physician competency with appropriate arthrocentesis techniques, the sensitivity and specificity of individual tests, the availability and proficiency of laboratories, and cost. Classification schemes have been established based upon gross, microscopic, biochemical, and microbiological analyses. The most traditional and cited classification for synovial fluid is normal, noninflammatory, inflammatory, septic, or hemorrhagic (Table 97-4).^{10,70,71,74} Despite the controversy that exists with guidelines and classification schemes, **it is critical to differentiate between an inflammatory and noninflammatory process, with the intent of expediting the diagnosis and treatment of a possible infectious etiology.**¹⁰

A detailed discussion of synovial fluid analysis is beyond the scope of this book. A brief discussion of the most essential components that can be performed in the ED will be presented.

TABLE 97-4 Synovial Fluid Analysis

	Normal	Noninflammatory	Inflammatory	Septic	Hemorrhagic
Gross analysis					
Color	Clear/yellow/straw	Straw/xanthochromic	Xanthochromic/cloudy/white	White/variable	Red
Clarity	Transparent	Transparent	Translucent/opaque	Opaque	Opaque
Viscosity	Very high	High	Low	Very low/variable	
Mucin clot	Good/firm	Fair-to-good/firm	Fair-to-poor/friable	Poor/friable	
Microscopic analysis					
Total leukocyte count (WBC/mm ³)	< 150	< 3000	3000–50,000	> 50,000	
Polymorphonuclear leukocytes (%)	< 25	< 25	> 70	> 90	
Biochemical analysis					
Glucose (mg/dL)*	Normal	Normal	70–90	> 90	
Protein (mg/dL)*	1.3–1.8	3–3.5	> 4.0	> 4.0	
Microbiological analysis					
Gram's stain	Negative	Negative	Negative	Positive [†]	Negative
culture	Negative	Negative	Negative	Positive [†]	Negative
Differential diagnosis					
		Osteoarthritis	Rheumatoid arthritis	Bacterial infections	Trauma/coagulopathy
		Traumatic arthritis	Acute crystal		Anticoagulant therapy
		Early rheumatoid arthritis	Synovitis		Tumor
		Avascular necrosis	Viral arthritis		Charcot's arthropathy
		Crystal synovitis [§]	Psoriatic arthritis		Hemangioma
		Osteochondritis dissecans	Reiter's syndrome		Arteriovenous malformation
		SLE	Arthritis of IBD		Sickle cell disease
		Polyarteritis	SLE		Postsurgical
		Scleroderma	Polyarteritis		Joint prosthesis
		Amyloidosis	Scleroderma		
			Amyloidosis		

IBD, inflammatory bowel disease; SLE, systemic lupus erythematosus; WBC, white blood cells.

[§]Chronic or subsiding.

PATHOPHYSIOLOGY OF SYNOVIAL FLUID

Synovium refers to the one to three cell thick structure that lines the joint space and terminates at the articular cartilage margin.⁷⁰ This structure overlies a highly vascularized subsynovium, both of which are supported by the dense fibrous joint capsule.⁷⁰ The synovium produces synovia, an ultrafiltrate of plasma that includes hyaluronate. The synovia serves to lubricate, nourish, and clear the metabolic waste of the avascular articular cartilage.⁷¹ Synovial fluid has been demonstrated to possess potent bactericidal activity against the most common gram-positive organisms responsible for septic arthritis.⁷⁵

The synovium has been described as a double barrier in which molecules must pass through the endothelial microvasculature as well as the synovium and its matrix.⁷¹ This double barrier is responsible for the retention of plasma protein. In the presence of an inflammatory process, the barrier is disrupted and protein can leak through the synovium. Difficulty arises in the diagnostic interpretation of protein and smaller molecules (i.e., sodium, chloride, urea, urate, lactate) found in synovial fluid secondary to the effects of damaged endothelial permeability and variable lymphatic drainage.^{71,73,74}

GROSS ANALYSIS OF SYNOVIAL FLUID

The color of synovial fluid varies depending on the amount of protein, blood, and breakdown products of hemoglobin. Normal synovial fluid usually appears clear to a straw or yellow color. Inflammatory and purulent synovial fluid may appear xanthochromic to white. Hemorrhagic synovial fluid is red and must be distinguished from a traumatic arthrocentesis. A traumatic aspiration usually clots and is more than often nonhomogenous.^{70,71} A hematocrit may be sent on a bloody aspirate to distinguish between a traumatic tap and hemorrhagic fluid. A vein was pierced by the needle (i.e., a traumatic tap) if the synovial fluid hematocrit is equal to the serum hematocrit.⁷¹

The following synovial fluid properties observed during bedside gross analysis were found to better predict a potentially septic joint when compared to synovial fluid cell count alone.⁶

The clarity of synovial fluid refers to the amount and type of particles within the fluid. Normal synovial fluid is usually transparent and newspaper print can be easily read through a glass tube containing this fluid.⁷⁰ Inflammatory and purulent synovial fluid is translucent to opaque secondary to the presence of leukocytes. Opaque fluid can also represent crystals and other particulate matter. Infected synovial fluid cannot be differentiated from noninfected synovial fluid based on gross appearance alone.¹⁰

Synovial fluid viscosity is determined by the intactness and concentration of hyaluronate. Viscosity can grossly be assessed by observing a drop of fluid fall from the tip of the needle. The “string” formed will normally be 5 to 10 cm in length.⁷⁶ In inflammatory and septic synovial fluid, the hyaluronidase is depolymerized and degraded.⁷¹ The string formed in these conditions is shorter, or not formed at all, and the fluid falls as a drop. Processes resulting in a significant effusion without inflammation may also dilute hyaluronate without degrading it and result in decreased viscosity. Clotted white blood cells may enhance viscosity in the presence of inflammation.⁷¹ EPs must be cautious with their interpretations of viscosity because even quantitative measures often fail to distinguish between inflammatory and noninflammatory states.¹⁰

The mucin clot test evaluates the degree of polymerization of hyaluronate.^{10,70} The mucin clot test is performed by one of two methods. The first method involves mixing the supernatant of a centrifuged specimen with a few drops of glacial acetic acid. The second method involves mixing 1 mL of synovial fluid to 4 mL of

2% acetic acid. A “good” clot consists of a dense white precipitant that indicates a high degree of polymerization and a high viscosity.⁷⁰ A “poor” clot consists of little to no precipitate and suggests an inflammatory process that has depolymerized the hyaluronate. Controversy exists concerning the subjectiveness of the clot’s endpoint.¹⁰

MICROSCOPIC ANALYSIS OF SYNOVIAL FLUID

The total leukocyte count, more than any other test, aids in distinguishing between an inflammatory, noninflammatory, and septic process.⁷¹ Although a significant overlap may exist, the total leukocyte count can be used to identify synovial fluid as normal, noninflammatory, inflammatory, or septic (Table 97-4). Using this classification scheme, a total leukocyte count of less than 3000 cells/L is considered noninflammatory. A count between 3000 and 20,000 cells/L is considered inflammatory. The range of 20,000 to 50,000 cells/L may be inflammatory or septic. A count greater than 50,000 cells/L is considered septic until proven otherwise. **The overlap between categories is considerable and clinicians must be cautious of basing a diagnosis solely on the total leukocyte count.** Depending on the acuteness of the inflammation, several arthritic conditions such as gout, pseudogout, and rheumatoid arthritis may yield a significantly elevated total leukocyte count approaching 100,000 cells/L.⁷² Immunocompromised hosts and some infectious diseases, such as tuberculosis and *Neisseria gonorrhoeae*, may have lower absolute counts than expected.¹⁰

The differential leukocyte count may further aid in distinguishing between inflammatory, noninflammatory, and septic synovial fluid. The cell count and WBC differential of the joint fluid is the best diagnostic test for septic arthritis, whereas the serum ESR and WBC perform poorer in the identification of infection.⁷⁷ However, using the traditional cut-off value of 50,000 WBC/mm³ lacks enough sensitivity to safely rule out a septic arthritis.⁷⁸ Inflammatory processes generally have greater than 70% neutrophils, whereas septic synovial fluid has greater than 90% neutrophils.⁷⁰ Again, the overlap can be significant depending on the arthritic process and its acuteness. Crystal-induced processes may present with high neutrophil counts, while immunocompromised hosts, fungal infections, and tuberculosis may present with lower neutrophil counts.^{10,72} **In general, a synovial fluid containing greater than 90% neutrophils in the presence of an elevated total leukocyte count should be highly suspicious of a septic process.** High eosinophil counts may suggest parasitic infection, allergic reactions, tumor, or Lyme disease.^{71,73} High monocyte counts may suggest viral infection (e.g., rubella and hepatitis B) or serum sickness.⁷⁶

Crystal identification is an essential component of synovial fluid analysis.^{79,80} Crystal identification requires the use of a polarized light microscope with higher-powered lenses and oil immersion capabilities. Crystals can be identified based on their shape, size, and birefringence. Birefringence is defined as the crystals’ ability to bend the light passing through it into two distinct directions, negative or positive. The light’s ability to bend negatively or positively is transformed into a specific color (e.g., yellow or blue) under the polarized microscope.^{70,71} Caution must be taken as artifact and tissue debris can often imitate birefringent material.

Crystal analysis requires an experienced technician and is rarely, if ever, performed in the ED. Monosodium urate crystals are commonly seen in gout. These crystals are needle-shaped, 2 to 25 µm in length, and have strong negative birefringence. They may clump together in sheets.^{76,81} Local anesthetic solutions have the ability to dissolve monosodium urate crystals. Therefore, the joint cavity should not be penetrated with the needle when anesthetizing the skin and subcutaneous tissue.⁷² Calcium pyrophosphate dihydrate crystals are seen in pseudogout. These crystals are

rhomboidal or rectangular, 2 to 10 μm in length, and have weak positive birefringence.^{76,81} These crystals may be more difficult to detect than monosodium urate crystals because of the weaker birefringence. Cholesterol crystals may present in multiple forms and sizes. They are typically flat rhomboidal plates, 5 to 50 μm in length, and have both negative and positive birefringence.⁷⁶ Artifact “crystals” can be produced by a variety of substances. Corticosteroids can be detected weeks after injection and have variable shapes but no regular geometric form. Maltese crosses are strong birefringent particles that are secondary to multiple compounds such as talc powder, lipids, calcium oxalate, and dust.⁷⁶

BIOCHEMICAL ANALYSIS OF SYNOVIAL FLUID

As discussed previously under the pathophysiology section, difficulty arises with the interpretation of total protein secondary to the effects of damaged endothelial permeability and variable lymphatic drainage.⁷¹ In theory, the damage caused by an inflammatory process should increase the permeability of proteins into the synovial fluid. Multiple studies have shown that protein samples were only able to classify synovial fluid into an inflammatory or noninflammatory process in approximately 50% of the cases.⁷³ Furthermore, the total protein count was unable to differentiate among various groups of arthritides, including rheumatoid arthritis and osteoarthritis.¹⁰

Theoretically, inflammatory and infectious processes consume glucose and thus lower the level present in synovial fluid. One study has shown that glucose levels were able to classify synovial fluid into an inflammatory or noninflammatory process in less than 50% of cases.⁷³ In 50% of the septic joints analyzed, the glucose level was not significantly decreased. Another study reports glucose analysis having a sensitivity of 20% and specificity of 84% in detecting inflammatory joint disease.⁷⁴ Synovial fluid glucose levels can vary from serum glucose levels when taken less than 6 hours after oral intake.⁷³ These studies are just a few of many that confirm synovial fluid glucose levels are not reliable to diagnose or rule out a septic joint.

Other biochemical markers have been studied to elicit a marker to differentiate a septic from a nonseptic joint.⁸² These include lactate, lactate dehydrogenase, and numerous immunologic and inflammatory mediators. These biochemical markers, at present, are not sensitive or specific to rule out a septic joint. They are not recommended for routine synovial fluid analysis. Bacterial polymerase chain reaction (PCR) techniques with aspirated joint fluid are currently being studied and are theoretically superior tests, able to identify difficult-to-culture organisms. However, many drawbacks, including high false positives due to contamination, limit usage until further studies are done.⁷⁸

MICROBIOLOGICAL ANALYSIS OF SYNOVIAL FLUID

The Gram's stain is an easily performed test that yields rapid results and can lead to the expedient diagnosis and treatment of a septic joint. The Gram's stain has a sensitivity of 50% to 70% for nongonococcal infections and less than 10% for gonococcal joint infections.⁷⁴ Although the sensitivity of this test is low, the specificity of the Gram's stain approaches 100%. This makes it an essential component of routine synovial analysis. *Neisseria gonorrhoeae* is identified as a gram-negative intracellular diplococcus.⁸³ *Staphylococcus aureus* and *Streptococcus* are responsible for approximately 70% of nongonococcal septic arthritis and can be identified as gram-positive cocci in clusters and gram-positive cocci in chains, respectively.^{57,81,84,85} Recent studies have identified an increased prevalence of methicillin-resistant *S. aureus* (MRSA)-associated osteoarticular pathology such as septic arthritis and subperiosteal

abscesses.⁶⁹ These diagnoses should be considered in patients with and without risk factors for community-acquired MRSA infection.⁶⁹

Bacterial identification is essential when confronted with the possibility of a septic joint. Synovial fluid cultures have a sensitivity of 75% to 95% for nongonococcal bacteria and 10% to 50% for gonococcal bacteria in the absence of previous antibiotic treatment. Difficulty arises from the low sensitivity of cultures for some organisms, culture methods, specimen preparation, and the length of time for some bacteria to grow.⁷⁴ Recent advances with the use of PCR techniques have shown increased sensitivity and specificity for detecting *N. gonorrhoeae*.^{70,83}

SPECIMEN COLLECTION

Minimal quantities of synovial fluid can yield valuable information. Analysis can be performed with as little as two drops of synovial fluid.⁷² The total leukocyte count, differential leukocyte count, crystal analysis, and Gram's stain can be obtained from the first drop, while the second drop can be sent for cultures.⁷² Unfortunately, few institutions or laboratories can perform synovial fluid analysis with only two drops of fluid.

The specimen may be transported for analysis by one of two methods. First, the syringe with the synovial fluid may be capped and sent to the laboratory. The laboratory technicians will then divide the specimen for analysis. Alternatively, the synovial fluid may be placed into tubes. A new sterile needle, different from the arthrocentesis needle, should be used to place fluid in the test tubes. A needle used for steroid injection should never be used secondary to the formation of a crystal-like substance.¹⁰ Synovial fluid for microscopic analysis should be collected in test tubes with and without preservatives. Fluid should be placed in a Culturette or culture bottle for microbiological analysis. Synovial fluid for crystal analysis should be sent in a test tube with liquid heparin (e.g., green-topped tube) because EDTA and powdered anticoagulants interfere with crystal identification.⁷² A tube (e.g., red-topped) containing no preservatives should be used to test for chemistries, serology, and viscosity. A tube with an anticoagulant (e.g., purple-topped tube) is used for the cell count, cell differential, and cytology. Prompt examination of fluid specimens is urgent to avoid the following problems: misdiagnosing borderline inflammatory fluids because of decreased WBC counts, not identifying crystals that dissolve with time, or overinterpreting findings because of new, artifactual crystals.⁸⁶

SUMMARY

Arthrocentesis is used to diagnose and make treatment decisions regarding a joint. It is a safe, easy, and simple procedure. Arthrocentesis is relatively painless and extremely beneficial to the patient. It may be performed for diagnostic information and/or therapeutic treatment. Analysis of the synovial fluid provides unique and valuable information about a joint. It is the only method to accurately and definitively diagnose or rule out a septic arthritis. Arthrocentesis is indicated to evaluate the cause of an arthritis or a joint effusion. All patients presenting with an acute monoarthritis or an acute, nontraumatic effusion should undergo arthrocentesis when the diagnosis is not clear based on the history and physical examination.

Methylene Blue Joint Injection

Pholaphat Charles Inboriboon and
Katherine Gloor Willet

INTRODUCTION

Trauma can breach the integrity of the joint capsule and result in infection, long-term arthritis, and other serious potentially permanent morbidity. Any breach of the joint capsule can introduce contaminants and risk septic inoculation of the joint. Synovial joint fluid provides nutrition to the articular cartilage. Loss of this fluid without prompt joint capsule closure can lead to cartilage wasting and arthritis. The injection of joints with methylene blue provides a rapid and definitive way to assess joint capsule integrity in cases of periarticular trauma where the clinical examination is inconclusive.

ANATOMY AND PATHOPHYSIOLOGY

Synovial joints (e.g., the fingers, wrist, shoulder, and knee) consist of a fibrous capsule that overlies a thin and delicate synovial membrane (Figure 98-1). The synovial membrane is a highly vascular structure and the site of synovial fluid production. The synovial

FIGURE 98-1. The anatomy of the knee joint.

fluid provides nutritional support to the relatively avascular articular cartilage. Joint capsules contain varying volumes of fluid that can be greatly expanded under conditions of inflammation or infection.

Methylene blue is a relatively safe and stable deep blue dye used in both chemistry and medicine. It is frequently used to treat methemoglobinemia and for marking skin and lymphatic tracts for oncologic surgery. The proposed basis for its vasoconstrictive effects is its ability to be readily oxidized.¹ Undiluted methylene blue can cause direct tissue necrosis without prior immune sensitization.²

The literature regarding the safety of methylene blue supports its use, even during direct intradermal injection. When used for lymph node mapping by direct intradermal and intraparenchymal injection, there is consistent evidence of local inflammatory reactions ranging from local wheal and flare in 0.5% of patients to focal erythema with induration in 5% of patients.^{3,4} Superficial tissue toxicity occurred in only 1.25% of patients.⁴ These reactions were proportional to the concentration of methylene blue ranging from a dilution of 1:1 to 1:7 and the superficiality of the injection.⁴ **Emergency Physicians (EP) need to be aware of the potential complications of methylene blue. The tissue toxic effects are believed to be much less for intraarticular injections than direct intradermal injection.**

INDICATIONS

The primary indication for injecting a joint with methylene blue is to assess the integrity of the articular joint capsule (Figure 98-2). This includes any of the following injuries in proximity to a joint: skin laceration, a visible joint capsule through a wound, an open fracture, extravasation of serous or serosanguineous fluid from a wound, or a traumatic loading of the joint with evidence of a deformity or an acute effusion. The finger, wrist, elbow, shoulder, toe, ankle, knee, and hip joints can all be injected with methylene blue.

CONTRAINDICATIONS

There are few absolute contraindications to injecting methylene blue into a joint. It should be avoided in patients with a known allergy to methylene blue or patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Patients with G6PD deficiency do not generate sufficient NADPH to efficiently reduce methylene blue to leukomethylene blue. This makes them prone to methylene blue-induced hemolysis, oxidative hemolysis, and hemolytic anemia. Methylene blue can itself initiate methemoglobin formation. It is reasonable to consider using a saline load test in patients with a contraindication to methylene blue or if methylene blue is not

FIGURE 98-2. Methylene blue dye injection into a knee joint. The loss of capsule integrity allows the dye to flow out of the joint cavity.

available.^{5,6} This involves the joint injection of a high volume of saline to stretch the joint capsule and watch for extravasation. It may be more difficult to appreciate extravasation of saline without dye. Methylene blue should not be injected intraspinally or intrathecally.

There are a few relative contraindications to the injection of methylene blue. Any joint injection should be used cautiously in a patient with a known coagulopathy, especially a factor deficiency, to prevent intraarticular hemorrhage. Consider reversing the coagulopathy before the injection. Methylene blue injection should not be performed if there is a lack of procedural knowledge or skill by the EP.

Not all synovial joints can be injected due to structural instability. Joint injection is often unnecessary when definitive operative treatment of the joint is indicated. This includes a visibly open joint capsule, a fracture with obvious joint involvement, intraarticular air on radiographs, and an intraarticular foreign body.

The articular capsule will be breached in many injuries but not externally open to the environment if there is no wound tracking to the skin surface. These injuries may present with an acute joint effusion or radiographic evidence of a periarticular fracture with or without intraarticular air. Methylene blue is not helpful in such cases despite capsular rupture.

Use caution when using methylene blue on psychiatric patients or those taking psychiatric medications.^{7,8} Methylene blue has potent monoamine oxidase inhibitor properties. It can react with certain psychiatric medications to cause a serotonin syndrome (**Table 98-1**). This adverse interaction has not been documented in the literature with the intraarticular instillation of methylene blue.

EQUIPMENT

- Sterile drapes
- Sterile gloves
- Sterile gown
- Face mask
- Eye protection
- Povidone iodine or chlorhexidine solution
- Sterile gauze
- Sterile dressing or tape
- Sterile saline
- Sterile basin
- Local anesthetic solution (e.g., 1% or 2% lidocaine)
- 25 or 27 gauge needles for infiltrating local anesthetic
- 18 or 21 gauge needles for joint injection
- 5 mL syringes for local anesthetic injection
- 10 mL syringes for fingers or toe injection
- 30 mL syringes for wrist or elbow injection
- 60 mL syringes for hip, knee, or shoulder injection
- 1% methylene blue dye
- Ultrasound machine (recommended)
- Sterile ultrasound gel
- Sterile ultrasound transducer cover
- Linear transducer with small footprint

PATIENT PREPARATION

A complete history and physical examination should be performed prior to the injection of methylene blue. The affected joint should be thoroughly assessed. Inspect the skin overlying the joint for breaks, infection, old scars, prior incisions, superficial lesions, or any wounds. Palpate the joint to identify any warmth, tenderness, or effusion. Evaluate the joint for any crepitation, deformity, ligamentous instability, or limitations in motion.

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Consent the patient for both the arthrocentesis procedure (i.e., joint injection) and the use of methylene blue. Obtain a written consent from the patient or their representative. Place the consent in the medical record.

Prepare the ultrasound transducer if using ultrasound with the procedure. Have an assistant apply ultrasound gel over the footprint of the transducer. Instruct the assistant to place the gel-coated ultrasound transducer in the sterile cover while you hold it. Have the

assistant place sterile ultrasound gel over the patient's joint. Reidentify the target.

Position the patient based on the specific joint to be injected and the planned approach. Expose the joint, the wound, and the surrounding areas. Identify the anatomic landmarks required for proper needle placement. The landmarks may be difficult to identify on a swollen and tender joint. Compare the "affected" joint to the "normal" joint on the opposite side of the body. Identify the joint and a landmark on the normal joint and transfer this to the affected joint. The injection of the joint should be ideally performed through a site that is not adjacent to the wound (**Figure 98-3B**). Leakage from the injection site into the wound could lead to a false-positive dye extravasation. **Avoid injecting through skin that is infected.**

Prepare the skin. Clean any dirt and debris from the skin. Scrub the needle insertion site with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes or a clear sterile dressing to maintain sterility of the injection site (**Figure 98-3**). The rate of infection resulting from intraarticular injections is very low if sterile technique is used.⁹

A comfortable and relaxed patient will facilitate arthrocentesis. Tense muscles can distort the anatomy of the joint and make palpation more difficult. Oral analgesics for the precipitating injury along with adequate local anesthesia for the procedure are often sufficient. The articular cartilage has no intrinsic pain fibers. The synovial membrane, joint capsule, and skin are richly innervated. Adequate time should be taken for the infiltration of local anesthetic solution. The subcutaneous injection of local anesthetic solution is often most practical for larger joints (e.g., the knee, shoulder, and hip). A regional block is often easier for small and more distal joints (e.g., the finger, ankle, and toe).

The administration of local or topical anesthesia is recommended but not required. The most common local anesthetic used is a short-acting injectable anesthetic solution of 1% lidocaine. There is disagreement regarding whether the additional needle stick to administer the anesthesia causes as much discomfort as performing the procedure without any anesthesia. This decision is specific to each EP and patient. Topical anesthetics (e.g., LET [lidocaine, epinephrine, tetracaine] or EMLA [eutectic mixture of local anesthetics]) can be considered, but the time it takes to achieve anesthesia can delay prompt evaluation of the joint.

Alternative methods of anesthesia include ice and topical vapor coolants. A sterile drape may be placed over the prepped skin and

a bag of ice water placed over the drape. Remove the ice water bag and drape after 5 minutes and perform the procedure. Ethyl chloride topical vapor coolant may be used as an anesthetic. Spray the solution onto the area of skin in which the needle will be inserted. Apply the spray from 6 inches above the skin. Spray until the skin turns white and frosty. This usually takes 5 to 10 seconds. Immediately perform the procedure as the anesthesia lasts only 30 to 60 seconds.

It is common to dilute the dye in normal saline before the injection. Draw up one to two drops of 1% methylene blue into an appropriately sized syringe. Fill the remainder of the syringe with sterile saline to dilute the dye.

TECHNIQUES

THE BASIC TECHNIQUE

The use of musculoskeletal ultrasound is useful to assist in arthrocentesis and has been shown to have many benefits including greater fluid aspiration, greater physician confidence, and greater accuracy.^{10,11} It does not result in more pain for the patient and takes minimal additional time to perform at the bedside. Bone will appear hyperechoic and easily differentiated from muscle and subcutaneous tissue. Tendons will appear fibrillar like a bundle of drinking straws. Joint fluid will appear hypoechoic and dark. The "seagull sign" is a shape that can be seen on most joint images (**Figure 98-4**). It represents the joint space between the articular surfaces of two opposing bones (**Figure 98-4**). It is a V-shaped hypoechoic area surrounded by hyperechoic bone. The needle can be inserted with or without ultrasound guidance once the landmarks are identified.

Apply the needle to the syringe and break the resistance. This helps avoid any sudden and painful movements of the needle within the joint cavity. Stretch the skin over the site where the needle will be inserted. Penetrate the skin briskly with the needle and enter the joint cavity. Gently aspirate synovial fluid to confirm the proper needle position within the joint cavity. If bone is encountered, slightly withdraw the needle and advance it in a different direction. Grasp and stabilize the hub of the needle with your fingers or a hemostat. Remove the syringe and attach the one with methylene blue.

Inject the methylene blue slowly into the joint cavity. There should be no resistance to flow if the needle is within the joint capsule.

A

B

FIGURE 98-3. An injury at the level of the knee joint. The patient is prepared by draping the lateral joint where the needle will be inserted (**A**) or by dressing the area with a sterile clear dressing (**B**).

FIGURE 98-4. Ultrasound of a joint. Note the “seagull sign,” which is a V-shaped hypoechoic area surrounded by hyperechoic bone. (Used from Devit Dilmen from www.commons.wikimedia.org.)

The injection should not be painful if the needle is within the synovial capsule. The patient may feel a slight discomfort as the joint capsule fills with fluid. Observe the skin wound for extravasation of blue dye while injecting the joint. Remove the needle when the procedure has been completed. Apply a bandage to the skin.

Different joints will accommodate various amounts of injected volume. The knee may allow for 30 mL or more, whereas the finger may accommodate only 1 mL of fluid. Often, it is only necessary to inject a minimal amount of dye before extravasation is seen. If the joint capsule is ruptured, a greater amount of fluid can be injected, as it will escape through the breach. The capsule will expand in intact joints. This results in increasing pressure and resistance to continued injection. There is often visible swelling of the skin around the injected joint if there is no breach.

SPECIFIC SITES

Methylene blue joint injection can be reasonably accomplished at any joint. The concern for joint capsule rupture without the concomitant need for operative exploration and fixation is rare in joints other than the knee and fingers. The knee is relatively easy to inject while the fingers and toes are more difficult. Arthrocentesis with methylene blue injection in the knee and finger is discussed below. The principles and techniques described can be used on any synovial joint for which there is concern of a capsule breach and for which the EP feels competent to perform arthrocentesis (Chapter 97).

■ PATELLOFEMOROTIBIAL JOINT (KNEE), PARAPATELLAR APPROACH

Landmarks: The knee joint can be injected in a variety of locations and with the knee extended or flexed. Palpate the superior, lateral, and inferior borders of the patella and the patellar tendon (**Figure 98-5A and 98-5B**). Identify the midpoint of the lateral or medial border of the patella (**Figure 98-5B**). Either of these landmarks may be used as the site for needle insertion.

Patient positioning: Place the patient in a position of comfort. Ideally, position the patient supine with the affected knee fully extended.

Needle insertion and direction: Insert an 18 gauge needle just below the midpoint of the lateral or medial border of the patella (**Figure 98-5C**). Direct the needle perpendicular to the long axis

of the leg and aimed toward the intercondylar notch of the femur. Advance the needle to a depth of 1 to 2 cm and aspirate until synovial fluid is obtained. Inject the methylene blue dye.

Ultrasound transducer placement: Start with transducer placement longitudinally and lateral or medial to the patella for a first view of the possible fluid collection. Change the transducer to a horizontal orientation. Rotate the transducer like the hands of a clock around the patella 360° to discover the area with the largest anechoic fluid collection. Advance the needle into the fluid space under ultrasound guidance. Grasp and stabilize the hub of the needle with your fingers or a hemostat. Inject the methylene blue.

Remarks: The blind lateral and medial parapatellar approaches are used with high relative success. This is most likely due to the large joint space and minimal accessory structures. Pooled studies demonstrate an overall lower success rate with the blind medial midpatellar approach (64%) compared with the blind superior lateral patellar approach (87%).¹¹ Success was increased with the use of ultrasound.¹¹

Joint injection: The volume injected into the knee joint is a topic of debate. Some studies suggest that 150 to 180 mL may be necessary for ruling out joint capsule involvement.^{5,6} The additional injection is not necessary once extravasation is noted.

■ METACARPOPHALANGEAL (MCP) JOINT

The relatively thin dermal and subcuticular layers over the phalanges often make one wonder about deep soft tissue avulsions or lacerations and the potential involvement of the joint capsule. Injection with methylene blue is an ideal method to assess joint capsule integrity. The success rate of arthrocentesis is much lower in the phalangeal joints than larger joints. The overlying ligaments and tendons are more prominent and the synovial capsule is smaller. A failure rate of 15% for finger arthrocentesis was found among skilled surgeons and as high as 32% among first-year residents.¹² Successful arthrocentesis was highest in the proximal interphalangeal joint compared to the distal interphalangeal joint or carpometacarpal joint of the thumb.¹²

Landmarks: Identify the MCP joint and the extensor digitorum tendon (**Figure 98-6A and 98-6B**). The MCP joint can be located just proximal to the prominence at the base of the proximal phalanx of the finger. Identify the extensor tendon by having the patient extend the finger against resistance.

Patient positioning: Place the patient sitting upright or supine on a stretcher. Pronate the hand and abduct the fingers. Grasp the finger and apply distal traction.

Needle insertion and direction: Insert a 22 gauge needle into the dorsal joint space just medial or lateral to the extensor tendon (**Figure 98-6C**). Direct the tip of the needle toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm. Inject the methylene blue.

Remarks: The application of distal traction often causes a depression to appear on both sides of the extensor tendon. These depressions can be used as landmarks for the site of needle insertion into the joint cavity.

Joint injection: A maximum volume of 1 mL may be instilled into this joint.

ASSESSMENT

The lack of methylene blue extravasation reassures the EP of an intact joint capsule. Extravasation of methylene blue through the injury site is indicative of a ruptured joint capsule. These require exploration, high-volume irrigation, and adjunctive medical treatment (e.g., antibiotics). Although some wounds can be closed primarily in the Emergency Department after consultation with an

Orthopedic or Hand Surgeon, open joints require management in the Operating Room.

A minimal amount of methylene blue needs to be injected before visible extravasation will occur. Upon injection, if no extravasation occurs, attempt to aspirate fluid. This may be difficult in small joints. Aspiration of blue fluid provides additional confirmation of intracapsular needle placement. **Maintain a high index of suspicion for a joint capsule rupture in the face of a negative study given the significant rate of ectopic needle placements (i.e., extrasynovial, intraligamentous, or intratendinous).** Clinical intuition and judgment should guide all decisions. Methylene blue injections may not be sensitive enough to identify violation of the joint capsule and may lead to an unacceptable rate of false negatives in the setting of puncture or stab wounds.¹³ Patients needed injections of up to 155 mL of fluid to obtain a positive result in 95% of subjects in a study looking at 1 cm arthroscopic incisions and methylene blue testing.⁵

AFTERCARE

Arthrocentesis with methylene blue is a relatively benign procedure. The postprocedural care consists of monitoring for external bleeding and swelling. Musculoskeletal and neurovascular checks should

be performed at the area and distal to the joint. Apply a bandage to the injection site. Pain should be minimal, and analgesia can be achieved with oral nonsteroidal anti-inflammatory drugs (NSAIDs). The patient may already be receiving opioid analgesics in the setting of a significant traumatic injury. Warn the patient or their representative that urine excretion of methylene blue can change the color of their urine.¹⁴

COMPLICATIONS

Complications are rare and include hemarthrosis, nerve injury, tendon injury, cartilage damage, and infection. External bleeding and nerve damage should be immediately apparent. A hemarthrosis may be insidious, appear with progressive swelling and pain with joint motion, and often without joint warmth. Tendon and cartilage damage may not be apparent for some time and may present with joint stiffness or arthritis. Septic arthritis is the most concerning complication, evidenced by swelling, erythema, warmth, pain with range of motion, and systemic symptoms. Cellulitis may also complicate the procedure and appear with local warmth, erythema, and induration over the site. Refer to Chapter 97 for a more complete discussion regarding the complications of arthrocentesis.

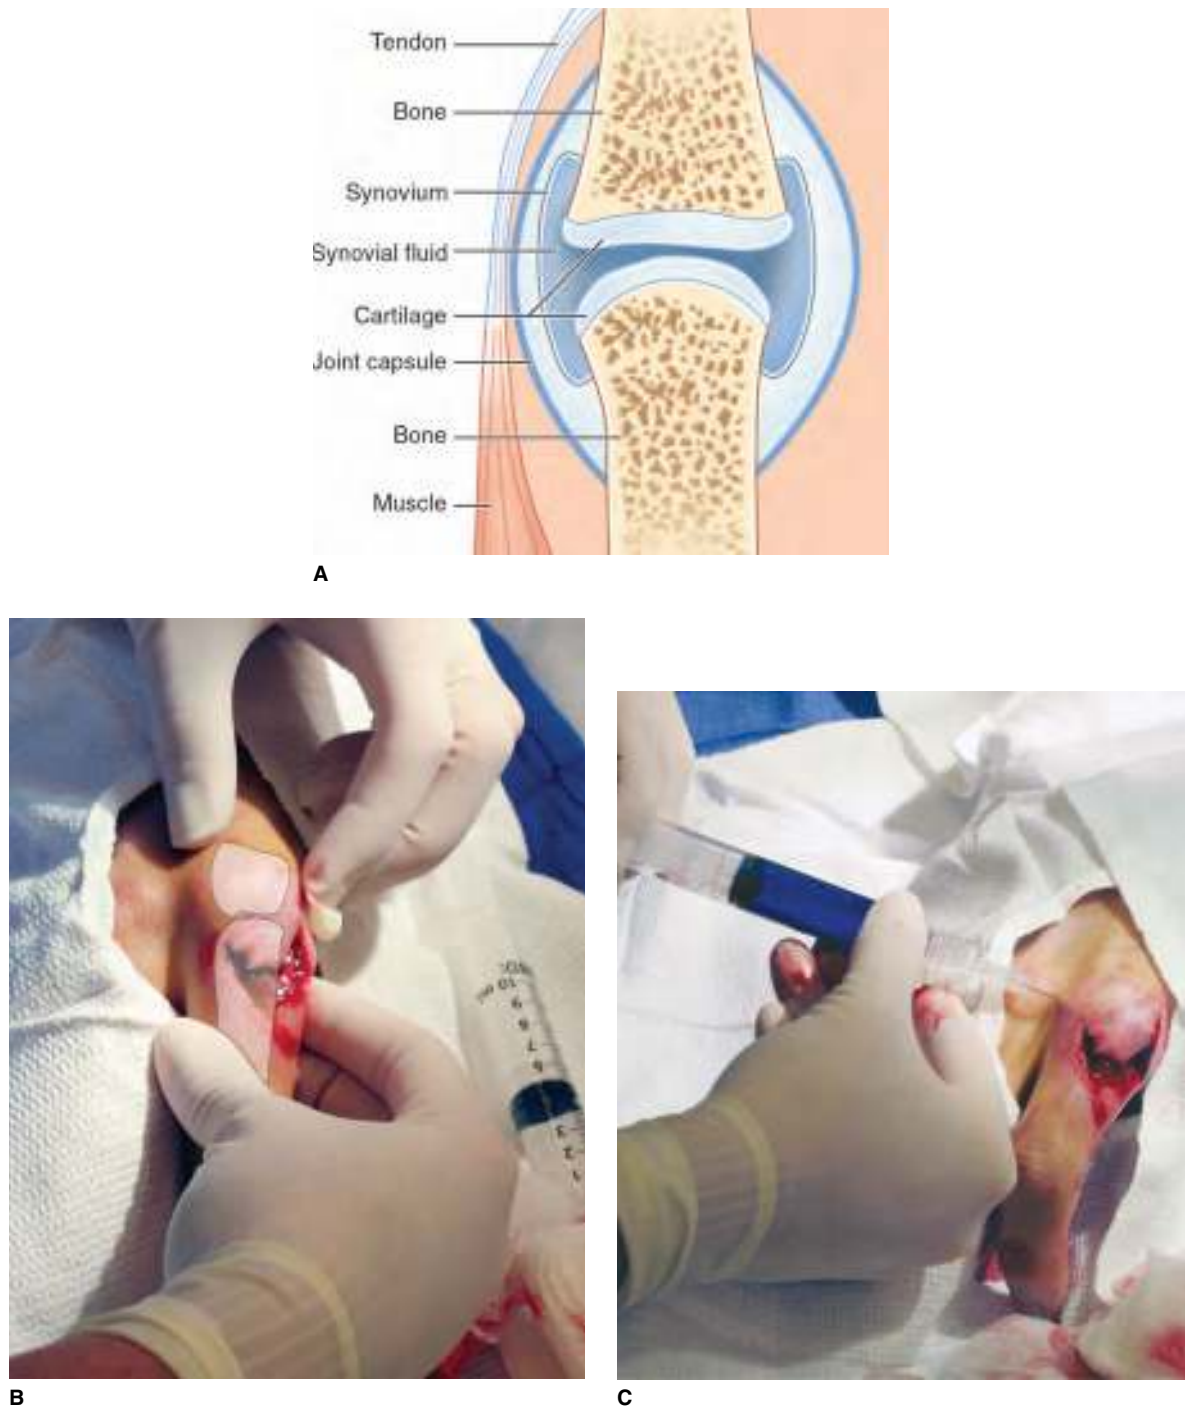

FIGURE 98-6. Methylene blue injection of the metacarpophalangeal (MCP) joint. **A.** Anatomy of the region. **B.** Palpation of the MCP joint. **C.** Injection of methylene blue.

SUMMARY

Synovial joint injection with methylene blue provides the EP with a simple, rapid, and definitive method of assessing joint capsule integrity in cases of periarticular trauma. Ultrasound may be useful to improve success rates in some joints. This procedure can help to determine between repairing a wound and sending the patient home or admitting a patient to the hospital for joint exploration and closure. Joint injection with methylene blue has a low rate of complications.

Basic Principles of Fracture and Joint Reductions

Scott C. Sherman and John Hardwick

INTRODUCTION

Orthopedic injuries are some of the most common presenting complaints facing the Emergency Physician (EP). Forces that cause injury can be large enough to result in fractures, displaced fractures, and joint dislocations. While each injury is different, some general principles can be applied to all displaced fractures and joint dislocations. Specific instructions on the techniques to reduce common fractures and dislocations are in Chapters 101 through 113.

ANATOMY AND PATHOPHYSIOLOGY

The most common reason for a fracture to be displaced or a joint to be dislocated in a particular direction depends on the mechanism of injury. A fall forward on an outstretched arm is the most common mechanism of injury of the upper extremity. It results in elbow dislocations occurring most frequently in a posterior direction. Distal radius fractures occur most often as Colles fractures, and supracondylar fractures are extension-type fractures in 95% of cases.¹

The deforming forces of muscles and ligaments play an important role in the appearance of a fracture. The muscles surrounding a fracture contract or spasm. This leads to further deformity (e.g., shortening, angulation, and rotation) of the bone fragments distal and proximal to the fracture. The bone fragments will displace in different directions depending on the location of a fracture (**Figure 99-1**). Fractures that occur between the insertions of the pectoralis major and deltoid muscles will result in a proximal humerus that is adducted from contraction of the pectoralis major muscle and a distal humerus that is abducted from contraction of the deltoid muscle (**Figure 99-1A**). The proximal humerus will be abducted from contraction of the deltoid muscle and the distal humerus will be adducted from contraction of the biceps and triceps muscles if the fracture occurs distal to the deltoid insertion (**Figure 99-1B**).

INDICATIONS

The reduction of fractures and joint dislocations in the Emergency Department (ED) is more frequently indicated than it is contraindicated. **Reduction is more readily achieved soon after an injury.** No fracture benefits from a prolonged period of angulation or displacement because the reduction becomes more

FIGURE 99-1. The direction of fracture displacement is influenced by muscle contraction following the injury. **A.** Humeral shaft fracture between the insertions of the deltoid and pectoralis major muscles. Arrows represent the direction of pull on the fracture fragments. **B.** Humeral shaft fracture distal to the deltoid muscle insertion.

difficult the longer the fracture has been present. No joint benefits from a prolonged dislocation as damage to articular cartilage increases with time.

Reduction should occur on an emergent basis when perfusion to the extremity is absent. A nonperfused extremity has a finite time before nerve and muscle death occurs. Reduction should occur as soon as possible. **The earlier perfusion is restored, the better is the chance of avoiding tissue necrosis.**

Vascular injury can occur after any displaced fracture or dislocation. Note the presence of an expanding hematoma, absent distal pulses, or delayed capillary refill. Orthopedic injuries more commonly associated with vascular injury include knee dislocations, posterior sternoclavicular joint dislocations, and supracondylar fractures. The importance of early reduction and repair of vascular injuries is emphasized in knee dislocations. Up to 86% of patients will require an amputation if surgery is delayed more than 8 hours.²

Urgent reduction of displaced fractures and joint dislocations is indicated to reduce the incidence of other potential complications. The incidence of a compartment syndrome of the forearm is reduced by early reduction of displaced supracondylar fractures.³ Reduce a posterior hip dislocation in a timely manner. The likelihood of avascular necrosis rises exponentially from a rate of 5% with less than 6 hours of being dislocated to 50% with greater than 6 hours of being dislocated.⁴

Neurologic injury results from the original injury, traction on a nerve, or compression of a nerve. Patients may experience altered sensation, decreased sensation, and/or paresthesias. **These injuries require urgent reduction to decrease potential long-term complications.**

CONTRAINDICATIONS

Be aware of potential relative and absolute contraindications despite the potential advantages of early reduction of fractures and dislocations in the ED. Chronic or previously unrecognized dislocations are difficult to reduce in a closed manner and overly forceful

attempts increase the chances of causing a fracture. An example is a surgical neck of the humerus fracture in a patient when attempting to reduce a chronic shoulder dislocation. **Reduction is contraindicated when the patient requires immediate operative treatment.** An open fracture in a perfused extremity should be reduced in the Operating Room where an appropriate surgical washout can occur.⁵

Not all displaced fractures and dislocations suspected of causing vascular injury should be reduced in the ED. An actual or suspected vascular injury associated with a posterior sternoclavicular joint dislocation is best performed in the Operating Room with a Cardiothoracic Surgeon available because the distal clavicle may be tamponading a lacerated subclavian vessel.⁶ Supracondylar fractures require immediate reduction only when the extremity is pulseless and perfusion is absent.⁷

Reduction is unnecessary when the potential for remodeling is such that the fracture angulation will correct without the need of a painful reduction or the risk of procedural sedation.^{8,9} Distal radius fractures in children heal well when they are 15° to 20° angulated.¹⁰⁻¹³ Other fractures where some degree of displacement or angulation may be acceptable and that frequently do not require reduction include fractures of the clavicle, humeral shaft, and neck of the fifth metacarpal.^{1,14-20}

Reduction may be contraindicated in the ED for numerous other reasons. Adequate analgesia may not be possible due to the patient's medical condition or the inability to appropriately monitor the patient. These cases may require general anesthesia in the Operating Room. It is prudent to consult and wait for an Orthopedic Surgeon when the potential complications of a reduction attempt are high or the EP is uncomfortable performing the technique. A busy EP in a chaotic ED with single coverage may not have the time or resources to adequately sedate a patient and reduce the fracture or dislocation. This situation may require calling in an additional EP or an Orthopedic Surgeon.

EQUIPMENT

- Procedural sedation equipment and supplies (Chapter 159), if applicable
- Hematoma block supplies (Chapter 155), if applicable
- Regional nerve block supplies (Chapter 156), if applicable
- Gurney
- Weights for distraction
- Bed sheets for traction-countertraction techniques
- Splinting/casting material or commercially made splints (e.g., knee immobilizer)
- Finger traps for upper extremity reductions
- Ultrasound machine and supplies
- Fluoroscopy, if available, to assist with the reduction and postreduction radiographs
- Assistants, depending on the reduction technique

PATIENT PREPARATION

Reduction techniques require a well-informed patient and a signed consent if possible. Explain the risks, benefits, and alternatives to the patient and/or their representative. Tell the patient what to expect. This knowledge may assist in the successful performance of the procedure. An anterior shoulder dislocation reduction can be performed with minimal or no sedation if the patient is able and willing to relax their musculature while the EP slowly manipulates the humeral head back into position.²¹ **Consent the patient for the**

anesthesia technique because this is a second procedure with potential complications much different from the reduction.

The physical preparation of a patient for the reduction of a fracture or dislocation is dependent on the type of injury and the clinical setting. The patient should be resting as comfortably as possible on a gurney. Place the patient supine whenever possible. Fully expose the involved extremity. Remove any constricting pieces of clothing or jewelry proximal and distal to the injury. Move the fluoroscopy unit into position if it is judged to be useful and is available. Splint material is frequently measured and set up prior to the start of the procedure so that it may be immediately applied to the extremity in the setting of an unstable fracture or dislocation.

Always consider a nerve block (Chapter 156) or hematoma block (Chapter 155) when approaching a reduction.²² Avoiding procedural sedation (Chapter 159) can result in better patient throughput, free nurses to complete other clinical tasks, and decrease the risk of procedural complications.^{4,6,14}

TECHNIQUE

The basic principles to reduce a displaced fracture or a joint dislocation are similar. The procedure can be divided into four steps.²³ **These are distraction, disengagement, reapposition, and release. The four steps can be used to reduce most displaced fractures or joint dislocations.**

The first step is distraction. It involves creating a longitudinal force to pull the fracture fragments or bones involved with a dislocated joint apart. Perform this step gradually. It sometimes requires time to be most effective in overcoming muscle spasm. Distraction is important when the fractured ends of the bone are overriding. It can be applied manually, with the help of an assistant, or by using weights. One common technique to distract the extremity injury uses finger traps to hold the hand or toes in place while weights are applied more proximally (**Figure 99-2**). Saline bags placed in a stockinette are equally effective and comfortable for the patient when weights are not available (**Figure 99-3**). Each liter bag of saline is equivalent to 1 kg or 2.2 pounds.

Disengagement is the second step to reduction. It allows for further disimpaction of the fracture fragments than distraction alone. Achieve disengagement by rotation of the distal fragment or more

FIGURE 99-2. Distraction for reduction of a forearm fracture.

FIGURE 99-3. Four 1 L bags of saline in a stockinette are the equivalent of 8.8 pounds. This setup is useful when weights are not available.

classically by “recreating the fracture deformity.” This relieves tension on the surrounding soft tissues to allow the interlocking fracture fragments to reposition (**Figure 99-4**). Disengagement is important for dislocation reduction. It is most frequently achieved by rotation of the bone distal to the joint. An example is the external rotation technique to reduce an anterior shoulder dislocation.

FIGURE 99-4. Disengagement and reapposition. Recreating the fracture deformity allows the release of interlocking fragments by lengthening and relaxing the soft tissue hinge.

FIGURE 99-5. Reapposition of a forearm fracture.

The third step is reapposition. This is achieved by reversing the forces that caused the injury to bring the bony fragments back into alignment (**Figures 99-4 and 99-5**). This step seems simple conceptually, but it may not be easy in clinical practice. One important pitfall to avoid is ignoring a rotational deformity that might create functional problems if the bone healed with a rotational deformity. This is especially important when treating fractures of the hand where a 5° rotational deformity of a proximal metacarpal fracture can translate into a distal fingertip that is 1.5 cm out of position (**Figure 99-6**).²⁴

Release refers to the removal of the initial distracting force with the intent that alignment will be maintained. It is at this point that forces such as muscle contraction and gravity return. The fracture fragments are at risk for becoming malaligned again. A properly applied splint or cast can protect from loss of fracture alignment. It is advisable to have the splint measured and ready to apply before manual reduction is initiated.

ALTERNATIVE TECHNIQUES

There are frequently alternative techniques or variations of the four steps outlined above that are available to the EP depending on the circumstance or the success of previous attempts. The next maneuver is attempted if the initial technique is unsuccessful. The authors use the following sequence of maneuvers to reduce an anterior shoulder dislocation: scapular manipulation with downward arm traction (i.e., disengagement and distraction), then external rotation (i.e., disengagement), followed by the Milch technique (i.e., disengagement), and finally traction-countertraction (i.e., distraction).^{21,25-28} **Be aware of the limitations of the closed reduction technique.** No amount of distraction and no alternative technique will reduce the dislocation without taking the patient to the Operating Room if soft tissue is interposed in an interphalangeal finger dislocation.

FIGURE 99-6. Rotational deformity of the fifth digit.

ULTRASOUND

Ultrasound has become increasingly useful in the diagnosis and management of fractures and dislocations. Ultrasound has proven to be an effective means of improving success of hematoma and nerve blocks which can eliminate the need for procedural sedation.^{5,12,13} Many dislocations and fractures can be reliably diagnosed using ultrasound. Ultrasound can be used to determine the success of reduction. This is useful when radiography or fluoroscopy is not available and the clinical examination is not definitive.^{1-3,11} The radiograph remains a mainstay of management and should not be abandoned in lieu of ultrasound.¹⁰

ASSESSMENT

Assess the neurovascular status of the extremity to ensure that pulses are present, the extremity is perfusing, and nerve function has not been compromised before and after any reduction attempt. Assess the neurovascular status after any casting or splinting to the extremity. Postreduction radiographs assess the success of the reduction, are used to identify any fractures that may have been missed on the prereduction radiographs, and assess any complications from the reduction.

AFTERCARE

Immobilize the extremity as required for the specific fracture or dislocation. Place a record of the procedure in the chart. Include any complications and the method of reduction. Obtain a repeat plain radiograph in most cases to document the success of the reduction. Refer patients with reduced fractures and dislocations to an Orthopedic Surgeon. A fracture that is properly reduced and immobilized will occasionally be unstable and become displaced again. This requires operative fixation.

COMPLICATIONS

Complications of fracture and dislocation reduction are uncommon when properly performed. Complications can occur with proper techniques. These include converting a closed fracture to an open fracture, soft tissue trauma that produces a compartment syndrome, a reduction attempt that causes injury to the soft tissues making the fracture more unstable, producing a fracture during the dislocation reduction attempt by using excessive force, neurovascular injury/compromise due to bony laceration, or compression of a nerve or blood vessel.

SUMMARY

Displaced fractures and joint dislocations requiring reduction are commonly seen in the ED. The initial step in assessment is to determine the neurovascular status of the extremity. Emergent reduction is the rule when neurologic or vascular compromise is present with few exceptions. All dislocations require reduction. Not all displaced fractures require reduction. Become familiar with displaced fractures that benefit from reduction. The basic elements of fracture dislocation and joint dislocation are distraction, disengagement, reapposition, and release.

Ultrasound for Fracture and Dislocation Identification and Management

Adrian Flores

INTRODUCTION

Point-of-care ultrasound (POCUS) for the evaluation of fractures and dislocations in the Emergency Department (ED) has been established in the literature and is not difficult to perform with minimal ultrasound (US) experience or brief focused training. Benefits include reduced cost, increased patient satisfaction, increased ED throughput, and decreased time to pain control.^{1,2}

Acute fractures and dislocations are frequently seen in the ED. Radiographs can be normal and the next step is computed tomography (CT) or magnetic resonance imaging (MRI). These modalities are expensive, time consuming, and may not be available. US is an option for the initial diagnosis. US has advantages over radiographs including multiplanar imaging, ability to be performed at the bedside, and no ionizing radiation.

US as an initial imaging modality may obviate the need for a radiograph in a patient with a low suspicion for fracture or dislocation. It can be done at the bedside at the time of the physical examination. The patient does not have to wait for a radiograph, would not incur the cost of a radiograph, is more likely to be happy with their care than if they had received no imaging at all, and receives no ionizing radiation.² Patients with a fracture often go on to require a radiograph to better characterize a fracture. There are circumstances (e.g., sternal fractures) where US can be more sensitive and a radiograph is unlikely to change patient management.^{3,4} Rapid evaluation with US allows the Emergency Physician to make a better and more specific choice to control pain. An intraarticular injection or a peripheral nerve block may be a better choice than intravenous (IV) opioids.

FIGURE 100-1. US of a typical bone.

This chapter covers the basics of US for long bone fractures and two of the most common dislocations in adults (e.g., the shoulder and elbow). Its use in other joint dislocations is similar.

ANATOMY AND PATHOPHYSIOLOGY

Bone is hyperechoic or bright white on the US screen and casts a dense shadow (Figure 100-1). The hyperechogenicity is from the differences in acoustic impedance between bone and surrounding soft tissues. The cortex is bright white and continuous, has posterior shadowing, and often shows a reverberation artifact. It is the brightest soft tissue structure seen on musculoskeletal US. This includes fascia, fat, muscle, subcutaneous tissue, tendons, and vessels. It can be brighter when the US transducer is directed transverse to the bone. The deep structures of the bone are not visible due to the high acoustic impedance of the cortex.

The rest of the musculoskeletal structures are visible adjacent and superficial to the bone. Fascial planes can be similarly bright as bone on US but do not produce a shadow. Air is visualized as bright and small scattered foci. It is not continuous like bone. Air casts a much dirtier shadow (e.g., various shades of gray and black) and not the uniform black shadow cast by bone.⁵

A bone fracture is visualized on US as a disruption of the hyperechoic bright white cortex of bone (Figure 100-2). This makes fracture identification easier in areas that are straight. A higher sensitivity and specificity are noted in these straight areas.⁶ There is often edema, hematoma, hyperemia on Doppler, and periosteal thickening surrounding the fracture. A healing fracture can show the callus that is forming at the fracture site on US.

INDICATIONS

An US is indicated in patients with a potential fracture or joint dislocation.⁷⁻¹⁷ It is helpful when reducing a fracture or joint dislocation.¹⁶⁻²⁰ An US is useful to evaluate a bone when a fracture is not seen on a radiograph but suspected on clinical examination.^{21,22} This is especially true for rib fractures when the chest radiograph is negative. When indirect evidence of fractures (e.g., fat pads on radiographs of the elbow or tenderness in the snuffbox) appears on radiographs, the fractures can often be seen on US. US can identify stress fractures when a radiograph is negative and saves the cost and time of a bone scan or MRI. The portability of US allows the athlete to be diagnosed in the field where there is no accessibility to radiographs and can identify a contusion which allows return to play versus a fracture. US can be used for persistent pain after an injury with negative radiographs or without radiographs. It may visualize a callus before the radiograph.

FIGURE 100-2. The cortical disruption seen in a fracture. **A.** Longitudinal view. **B.** Transverse view. (Used with permission from reference 6.)

US is ideal for close and overlapping small bones (e.g., the wrist and foot) to identify a fracture.

Evaluation of fractures and dislocations with US has the potential to take a much larger role, including as the primary diagnostic modality, in remote settings and low-resource settings. The portability of US allows for its use in remote military and wilderness settings where radiology equipment is too large and heavy. The World Health Organization (WHO) estimates that up to 75% of the population has no access to diagnostic imaging.²³ The low cost, portability, and bedside interpretation of US could potentially have a large impact.

CONTRAINDICATIONS

A contraindication to performing an US examination is an open fracture. Relative contraindications are issues that limit a thorough evaluation. Pain and tenderness are usually the only factors that limit an US examination. These can be overcome with the application of analgesics before the US examination proceeds.

EQUIPMENT

A brief description of the equipment required is provided in this section. A complete description is contained in Chapter 6, Basic Principles of Ultrasonography.

ULTRASOUND MACHINE

Most bedside US machines are portable machines on a cart. Many handheld devices are now available and may be suitable for evaluating fractures and dislocations.^{24,25} The machines vary greatly but have three basic buttons to obtain good images. The power button can sometimes be in a place that is not obvious or even hidden. The gain adjusts the brightness of the image. The depth determines how deep into the tissue the machine images. It allows the sonologist to bring the object into the middle of the monitor screen.

TRANSDUCER

The linear, high-frequency transducer (e.g., 6 to 15 MHz) is appropriate for most musculoskeletal applications. It is also known as the vascular transducer due to its common use for evaluation of vasculature for venous or arterial access. This transducer provides the best resolution for superficial structures. A lower frequency transducer (e.g., a phased array of 1 to 5 MHz or a curvilinear of 2 to 5 MHz) might be a better choice in circumstances requiring images deeper in the body (e.g., a femur in a patient with obesity or thick musculature).

ULTRASOUND GEL

Commercial US gels are widely available. Single-use sterile lubricant packets can be used in situations where there may be concern for introducing an infection. Locally made US gels have been proposed as an alternative in remote settings.²⁶

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain a verbal informed consent for the procedure. Raise the gurney to a comfortable height and lower the rail to be in a comfortable ergonomic position for scanning. The examiner stands on the patient's right side by convention with the US machine in front and near the patient's head. Constraints (e.g., room size and room configuration) sometimes do not allow for this positioning, and the Emergency Physician should use their best judgment. Warn the patient that the US gel might feel cold. Patients are often surprised by how cold the US gel feels despite it being at stored room temperature.

Have a clean towel available to wipe the US gel off the patient after obtaining images. Make the appropriate preparations to disinfect the US transducer after scanning.

FIGURE 100-3. Proximal phalanx fracture of the fifth finger. **A.** Radiograph. **B.** US showing the cortical disruption (arrow). (Used with permission from reference 28.)

TECHNIQUE FOR FRACTURES

Evaluation of fractures is straightforward. Evaluate the bone in two planes at 90° to each other. This usually comprises a transverse (i.e., short axis or cross-section) view and a longitudinal (i.e., long axis) view. Place the transducer with the marker pointed to the patient's right for short axis views. Place the transducer with the marker toward the head for long axis views. Start in the short axis and identify the

bone of interest. Rotate the transducer 90° to the long axis. Scan the bone from the distal to proximal portion. Pay special attention to the area of maximal tenderness.²³ **A fracture is identified by a cortical disruption or irregularity of the cortical line (e.g., depressions, displacements, or gaps).**^{6,27}

This same technique can be used for all bones.^{14,28-38} Scanning small bones of the hand (**Figure 100-3**), wrist (**Figures 100-4, 100-5, and 100-6**), and foot (**Figure 100-7**) through a 100 mL bag

FIGURE 100-4. Positioning of the transducer and normal US findings for the scaphoid. The cortex of the distal radius (arrowheads) and scaphoid (arrows) is noted in the US images. **A.** Longitudinal position over the lateral wrist with the hand ulnar deviated. **B.** Longitudinal view US. **C.** Palmar positioning with the hand ulnar deviated. **D.** Palmar US view. **E.** Dorsal positioning with the hand neutral. **F.** Dorsal US view. (Used with permission from reference 29.)

B

of normal saline or submerged in a water bath can facilitate obtaining a good image. The humerus, radius (**Figures 100-8, 100-9, and 100-10**), ulna (**Figure 100-11**), femur (**Figure 100-12**), tibia, and fibula (**Figure 100-13**) are easy long bones to evaluate using US. The clavicle (**Figure 100-14**), patella (**Figure 100-15**), and sternum (**Figure 100-16**) are easy non-long bones to evaluate because of their superficial location and the limited area needed to be scanned. Evaluation of the skull, mandible, ribs (**Figure 100-17**), metacarpals, phalanges, and metatarsals with confidence and accuracy takes more focused teaching and practice.³⁹

A few fractures deserve special mention. Rib fractures are commonly suspected. Radiographs are not sensitive in diagnosing a costal cartilage fracture, a costochondral junction fracture, or a minimally displaced rib fracture. US can diagnose these fractures.^{40,41} The transducer can move along the rib as it changes direction.³³ It is important to diagnose rib fractures for the patient's knowledge, expectations, pain management, and missing work. It can affect the discharge instructions to prevent atelectasis and pneumonia.

US can be used to evaluate subacute traumatic injuries to evaluate healing fractures (**Figure 100-18**).³³ Real-time US can help in the reduction of fractures.⁹ The use of US in children can save time, prevent them from leaving the department, and help build rapport.^{15,42} US can identify fractures not seen using radiographs (i.e., occult fractures).^{43,44}

TECHNIQUE FOR DISLOCATIONS

SHOULDER

The shoulder is the most commonly dislocated major joint in adults. Place the patient on the edge of the bed with their arm adducted and the elbow flexed to 90°. Stand behind the patient and position the US machine in front of the patient. Place the US monitor screen toward the examiner. Use the curvilinear transducer. Place it with the marker facing to the patient's left rather than the right because

FIGURE 100-14. Longitudinal US view of a clavicle fracture. Periosteal thickening (white arrowheads) and edema (black arrowheads) are noted. (Used with permission from reference 33.)

you are behind them and scanning posterior rather than anterior.^{45,46} Start scanning the posterior shoulder just inferior to the scapular spine (**Figure 100-19**). Slide laterally and identify the glenoid fossa and humeral head (**Figure 100-19**). The humeral head is displaced at least 20 mm from the glenoid fossa toward the far-field or bottom of the screen in an anterior dislocation (**Figure 100-20**). The humeral head will be displaced toward the near-field or top of the screen in a posterior dislocation (**Figure 100-20**).^{47,48}

US can be used to confirm the reduction in addition to the initial evaluation. The humeral head will be aligned with the glenoid fossa, and the shoulder should freely internally and externally rotate on the screen. This is especially helpful when using procedural sedation where a rapid evaluation with US can be performed much faster than radiographs. This limits the time for patient sedation and prevents the need for resedation if the radiograph shows a persistent dislocation.⁴⁷

This chapter does not cover shoulder reduction techniques (Chapter 102). It is important to note that US is extremely helpful in ensuring entry into the joint for intraarticular lidocaine injections. The intraarticular instillation of local anesthetics has been shown to be as effective as procedural sedation for analgesia for the reduction of anterior shoulder dislocations.^{49,50}

ELBOW

The proximal ulna often dislocates posterior to the distal humerus. Place the patient with their arm in 90° of flexion (**Figure 100-21**).⁵¹ Place the US transducer on the posterior aspect of the distal humerus in a longitudinal plane with the marker toward the patient's head (**Figure 100-21A**). Slide the transducer caudally until the olecranon is visualized. The olecranon is aligned with the distal humerus in a normal elbow (**Figure 100-22**). Turn the transducer 90° and repeat the US scan (**Figure 100-21B**). The olecranon is displaced posteriorly from the distal humerus or displaced toward the top of US monitor screen in a dislocation (**Figure 100-23**).⁵²

(Used with permission from reference 33.)

ASSESSMENT

Review and interpret the US scans. Physicians with a minimal US background and short focused training sessions can perform many US scans.^{23,25} A systematic review on the diagnostic accuracy of bedside US in the ED found an overall 85% to 100% sensitivity and 73% to 100% specificity.¹ The best option is to determine the scan inconclusive when there is uncertainty regarding the diagnosis or interpretation of the images. The use of US allows the Emergency Physician to continuously manipulate the fracture until it is reduced without the delays of obtaining radiographs and having to sedate the patient for a long time (Figure 100-24).

AFTERCARE

No specific aftercare is needed for the patient. Wipe the excess US gel off the patient. Wipe down and clean any blood, debris, and dirt from the US transducer. Disinfect the US transducer according to manufacturer directions and hospital policy.

COMPLICATIONS

US is operator dependent and the images can be misinterpreted. It depends on an individual's experience, training, and familiarity with the scan being performed. There are no other complications from obtaining a US scan of the affected area. Pain can be overcome by not pushing as hard with the transducer or providing IV analgesia before the scan.

Ensure the transducer is clean before and after scanning. A clean transducer before scanning will not cross-contaminate the patient. A clean transducer after scanning prevents the next patient from being contaminated. The US machine and transducer are used by multiple people in the ED. It is recommended to wipe the transducer with disinfecting wipes before and after scanning. Use wipes approved by the manufacturer and hospital infection control.

SUMMARY

US is as sensitive as radiographs for most long bone fractures and more sensitive for some fractures (e.g., sternum). Novice sonographers can learn these scans and apply them in clinical practice to

FIGURE 100-19. The steps in performing a shoulder US. View the humeral shaft (1-a and 1-b). Slide the transducer to view the humeral head (2-a and 2-b). improve time to pain control, choose a better pain control modality, reduce the number of unnecessary radiographs, decrease patient length of stay, and improve patient satisfaction. US can be used by the Emergency Physician in the ED or low-resource settings.⁵³

Sternoclavicular Joint Dislocation Reduction

Michael D. Burg

INTRODUCTION

Sternoclavicular dislocations are uncommon, accounting for less than 3% of shoulder girdle injuries.¹ The medial clavicle may be displaced anteriorly, posteriorly, or rarely superiorly (**Figure 101-1**).² Bipolar clavicular dislocations (i.e., simultaneous dislocation of both clavicular articulations) also occur rarely.³ Anterior dislocations are considerably more common than posterior dislocations. However, posterior dislocations deserve more attention due to the far higher incidence of associated complications.¹ Also, since the medial clavicular physis closes relatively late in life, what appears to be a posterior sternoclavicular dislocation in young patients may actually be a medial epiphyseal disruption with posterior displacement.⁴

Sternoclavicular dislocations result from direct trauma to the sternoclavicular joint or to the glenohumeral joint with the force directed toward the sternoclavicular joint. **Tremendous force is usually required to disrupt the sternoclavicular joint.** Common mechanisms of injury include motor vehicle collisions and contact sports.³ Falls, minor trauma, or various medical conditions without trauma result in sternoclavicular dislocations less commonly.⁵⁻⁷

Anterior dislocations are often due to indirect forces transmitted through the anteromedial shoulder. As the shoulder is externally compressed and rolled backward, the lateral clavicle is pulled back and down beyond its limit of motion. The first rib acts as a fulcrum to spring the sternal end of the clavicle anteriorly from its articulation (**Figure 101-2**).^{1,8,9}

Posterior dislocations may be due to direct or indirect forces.^{1,10-13} With indirect trauma, the shoulder is externally compressed and rolled forward from a force applied posterolaterally to the shoulder. The costoclavicular ligament acts as a fulcrum that produces displacement of the sternal end of the clavicle posteriorly from its articulation (**Figure 101-3**).¹¹ Less commonly, a posterior dislocation may be due to a direct blow to the anteromedial clavicle.¹²

FIGURE 101-1. Superior view of the position of the medial end of the clavicle in a sternoclavicular joint dislocation. (Used with permission from eOrthopod.org.)

FIGURE 101-2. Clinical photo of an anterior sternoclavicular joint dislocation. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill, 2016. Photo contributor: R. Jason Thurman, MD.)

Spontaneous and atraumatic sternoclavicular subluxations and dislocations do occur, often in those with laxity in other joints or in association with inflammatory conditions.^{7,8,14-16} Both anterior and posterior subluxations have been described, as have atraumatic anterior and posterior dislocations.¹⁴⁻¹⁶ These are usually seen in females less than 20 years of age with sternoclavicular joint laxity. The clavicle dislocates anteriorly during abduction or flexion of the arm to the overhead position and reduces spontaneously when the arm is returned to the side.

ANATOMY AND PATHOPHYSIOLOGY

Both surfaces of the maximally mobile sternoclavicular joint are covered by fibrocartilage (**Figure 101-4**). The intraarticular disk ligament divides the joint into two separate compartments, each of which is lined with synovium.¹⁷ This joint is freely mobile and functions like a ball-and-socket joint, with motion (including rotation) in almost all planes.^{1,18} This includes 30° to 35° of upward elevation, 35° of combined forward-backward movement, and 40° to 45° of rotation about its long axis.¹⁸ Less than half of the medial clavicle articulates with the sternum's upper angle, giving the sternoclavicular joint the least bony stability of any major joint.¹ Given this amount of joint incongruity, it is surprising that sternoclavicular joint dislocations are uncommon. However, the joint's stability is

FIGURE 101-3. CT scan of a posterior sternoclavicular joint dislocation. (Used with permission from Tintinalli JE, et al: *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*, 8th ed. New York: McGraw-Hill; 2016.)

FIGURE 101-4. Anatomy of the sternoclavicular joint and surrounding structures. The extremely strong posterior sternoclavicular ligament lies immediately behind the sternoclavicular joint and is not shown.

due to strong surrounding structures (**Figure 101-4**), including the intraarticular disk, the extraarticular costoclavicular ligament, the anterior and posterior sternoclavicular ligaments, and the interclavicular ligament.¹⁷

Numerous vital structures are directly posterior to the sternoclavicular joint including the trachea, esophagus, lungs, and great vessels (Figure 101-5). Injuries to these structures frequently occur with posterior sternoclavicular joint fractures and dislocations due to this proximity, the thoracic inlet's small size, and the forces involved.

The medial clavicular epiphysis is the last long bone epiphysis to appear, usually ossifying by 18 to 20 years of age, but occasionally not until the age of 25.^{1,19} It is also the last to fuse.^{1,19} This epiphysis is difficult, or frankly impossible, to see on plain radiographs. Many injuries in patients less than 25 years of age initially thought to be true sternoclavicular joint dislocations are actually Salter-Harris I or II epiphyseal injuries.^{1,20-24}

Sternoclavicular joint dislocation diagnosis may be difficult and/or delayed, particularly in those with multiple injuries.^{25,26} Several case reports exist detailing diagnostic delays, occasionally with catastrophic outcomes.²⁷⁻²⁹

Severe local pain that increases with movement of the ipsilateral arm may signal a sternoclavicular joint disruption. Edema, ecchymosis, crepitus, and tenderness may be present in the region overlying the sternoclavicular joint. Those with sternoclavicular joint dislocations usually hold their affected arm adducted across the trunk. A head tilt toward the affected side may be seen in an attempt to relieve the pain caused by traction of the sternocleidomastoid muscle on the medial clavicle.³⁰

With anterior dislocations, the clavicle's medial end may be palpable anterior to the sternum (**Figure 101-2**). It may be either fixed or mobile. With posterior dislocations, a depression may be visible or a hollow palpable over the region of the sternoclavicular joint.³¹ Edema may obscure these physical findings. The affected shoulder may be held forward. The affected shoulder may not lie flat against the bed when the patient is supine.

Additional signs and symptoms associated with posterior sternoclavicular joint dislocations may be due to mediastinal injuries.^{1,31-34} **Perform a careful and complete physical examination. Associated injuries are common.** Tracheal or esophageal compression may result in cyanosis, dyspnea, or dysphagia. Ipsilateral arm

circulation may be reduced if the subclavian artery is compressed or otherwise damaged. Venous congestion of the upper extremity or neck can result from compression of, or injury to, the subclavian or jugular veins. Shock may be due to compression or injury of the great vessels. Upper extremity paresthesias may result from brachial plexus injuries. Voice changes may be due to compression of the recurrent laryngeal nerve. Tracheal or lung injuries with resultant pneumothoraces can occur.

Do not rely on clinical findings gleaned from observation and palpation to distinguish between anterior and posterior sternoclavicular joint dislocations.¹ Appropriate radiologic studies are recommended prior to treatment decisions. Routine radiographs that include the sternoclavicular joint are difficult to interpret due to overlapping structures. Several different radiographic projections are reported to improve the ability to detect sternoclavicular joint asymmetry.^{1,11,12,35,36} Computed tomography (CT) is the optimal imaging modality for the sternoclavicular joint (**Figure 101-3**). It should always be performed if the diagnosis is uncertain.^{1,12,13} Ultrasound may also provide useful diagnostic and therapeutic information.³⁷⁻³⁹

With posterior sternoclavicular joint dislocations, consider appropriate studies to evaluate for injuries to neighboring structures. A chest radiograph may reveal mediastinal widening, pneumomediastinum, or a pneumothorax. An intravenous contrast-enhanced chest CT is definitive (**Figure 101-3**). It will reveal the relationship of the clavicles to the great vessels, esophagus, and trachea. The CT may also demonstrate compression of, or injury to, these structures as well as other findings. Angiography, venography, and Doppler studies can further investigate potential vascular injuries. The esophagus may be evaluated with esophagoscopy and/or an esophagram. Bronchoscopy is indicated if a tracheal or bronchial injury is suspected.

INDICATIONS

It was generally held that closed reduction should be attempted on all acute traumatic anterior and posterior sternoclavicular joint dislocations.^{1,15} A case series describes successful closed reduction of an anterior sternoclavicular joint dislocation 10 days after injury.¹¹ Successful closed reduction of posterior sternoclavicular joint dislocations has been reported up to 5 days after injury.³⁷ However, in at least one of these late-presenting cases, reduction was done in the Operating Room with ultrasound guidance.³⁷

FIGURE 101-5. Anatomic relationships of structures to the sternoclavicular joint. **A.** Anteroposterior view. **B.** Cross-section through the level of the sternoclavicular joint.

Early consultation with an Orthopedic Surgeon is recommended for the less common, potentially more serious, and difficult to manage posterior sternoclavicular joint dislocations. Prior to the reduction, carefully assess the patient's airway, breathing, circulation, and neurologic status. Obtain appropriate diagnostic imaging studies as described above. Obtain immediate Thoracic Surgery consultation for patients with intrathoracic injuries due to posterior dislocations. **Emergent reduction in the Operating Room with an Orthopedic Surgeon and a Thoracic Surgeon in attendance is required for those with mediastinal injuries due to posterior dislocations. If the consultants are not available, consider emergent reduction in the Emergency Department if neurologic or vascular compromise exists in the affected extremity.**

In patients under the age of 25, many sternoclavicular disruptions initially thought to be true posterior dislocations are Salter-Harris I or II epiphyseal injuries with posterior malposition of the distal clavicular segment.^{1,20-24} Closed reduction of these injuries can still be attempted after Orthopedic Surgeon consultation.

CONTRAINDICATIONS

Postpone reduction to attend to airway, breathing, circulation, and more serious injuries. If a posterior sternoclavicular joint dislocation is present and compromising adjacent structures, prioritize

reduction in your critical patient care actions. Open reduction of posterior sternoclavicular joint dislocations may be preferred if surgery is planned for associated injuries.

Chronic anterior dislocations should not be reduced in the Emergency Department.⁴⁰⁻⁴³ These patients usually have minimal discomfort, normal range of motion and can return to normal activity as tolerated.^{1,43} They generally do well with symptomatic treatments, nonsteroidal anti-inflammatory drugs, heat application, and a sling. However, a small number will develop persistent symptomatic instability requiring surgery.⁴⁰⁻⁴⁴

The reduction of chronic posterior sternoclavicular joint dislocations is controversial. Most will require an open procedure due to the long-term potential risk of damage to mediastinal structures.^{1,45,46} In asymptomatic young adults, a strategy of watchful waiting for physeal plate remodeling that removes the posteriorly displaced bone may be acceptable.^{1,34,47} Notably, chronic posterior dislocations without serious sequelae are reported.^{15,48} Treatment decisions for chronic posterior fractures or dislocations should be deferred to an Orthopedic Surgeon.

EQUIPMENT

- Sandbags or folded towels
- Povidone iodine or chlorhexidine solution

- Sterile towel clamps
- Sterile gloves
- Local anesthetic solution
- 18 gauge needles
- 25 gauge needles
- 10 mL syringe

PATIENT PREPARATION

Explain the risks, benefits, alternatives, potential complications, and aftercare of the procedure to the patient and/or their representative. Obtain a signed consent to perform the reduction.

Place the patient supine with the affected side near the gurney's edge. Place sandbags or towels between the patient's scapulae. They should be thick enough to raise the patient 5 cm off the gurney.¹

Anesthesia and analgesia are required to reduce a sternoclavicular joint dislocation. Closed reduction of an anterior sternoclavicular joint dislocation may be performed with local anesthetic solution infiltrated about the medial clavicle and sternoclavicular joint. Consider using supplementary procedural sedation and analgesia (Chapter 159). Posterior sternoclavicular joint dislocations have also been reduced using local anesthetic infiltrated about the medial clavicle and sternoclavicular joint. However, procedural sedation and analgesia (Chapter 159) or general anesthesia is highly recommended. Obtain a consent for the anesthesia technique used to reduce the dislocation.

TECHNIQUES

ANTERIOR STERNOCLAVICULAR JOINT DISLOCATION REDUCTION

Position the patient as described above. The patient's arms should be at their sides (**Figure 101-6A**). Administer analgesia and sedation as needed. Instruct an assistant to apply downward pressure to the anterior surface of both shoulders (**Figure 101-6B**). Pushing the shoulders posteriorly pulls the clavicles laterally and distracts the dislocated medial clavicle. Push the medial clavicle posteriorly and into anatomic position (**Figure 101-6C**). Clavicular relocation usually occurs promptly. Be aware that a sizeable percentage of these dislocations will immediately recur.^{1,40} Carefully sit the patient upright while the assistant maintains the patient's shoulders in a posterior position. Apply a figure-of-eight splint (**Figure 112-3C**).

FIGURE 101-6. Reduction of an anterior sternoclavicular joint dislocation. **A.** Patient positioning. **B.** An assistant applies anterior pressure to both shoulders. **C.** The medial clavicle is pushed posteriorly.

POSTERIOR STERNOCLAVICULAR JOINT DISLOCATION REDUCTION

Position the patient as described above. Administer anesthesia, analgesia, and sedation as needed. Abduct the affected arm 90° and extend it 20° in-line with the clavicle (**Figure 101-7A**). Spontaneous reduction may occur at this point. If not, instruct an assistant to apply distal inline traction to the extremity (**Figure 101-7B**). This may be aided by wrapping a sheet about the patient's upper torso to provide countertraction. The clavicle may reduce under traction. Keep the patient's arm abducted, extended, and under traction if the sternoclavicular joint does not reduce. Manually manipulate the clavicle into position. Grasp the medial clavicle and pull it upward (i.e., anteriorly) into anatomic position (**Figure 101-7C**).

It may be difficult to firmly grasp the medial clavicle. To overcome this problem, cleanse the skin overlying the medial clavicle of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply a towel clamp to grasp through the skin and around, and not through, the shaft of the medial clavicle (**Figure 101-7D**). **Ensure that the towel clamp follows the contours of the clavicle. Grasping too deeply can puncture the subclavian artery and/or vein.** Be aware that the clavicle's thick cortical bone often prevents purchase of the towel clamp into the clavicle.¹ Elevate the medial clavicle into anatomic position while an assistant maintains traction on the abducted and extended extremity (**Figure 101-7D**).

ALTERNATIVE TECHNIQUES

An alternate technique uses the first rib as a lever to reduce a posterior sternoclavicular joint dislocation and has been reported to be successful when the previous technique has failed.^{9,49} Position the patient supine with their arms adducted (**Figure 101-8A**). Administer analgesia and sedation as necessary. Instruct an assistant to apply distal in-line traction to the adducted arm (**Figure 101-8B**). This will lever the medial clavicle over the first rib and above the superior sternum (**Figure 101-8B, inset**). Apply posterior (i.e., downward) pressure to the anterior shoulder, forcing it into retraction (**Figure 101-8C**). This will lever the medial clavicle anteriorly and laterally into anatomic position (**Figure 101-8C, inset**). Reduction may occur at this point. If it does not, elevate the medial clavicle by one of the two methods (i.e., grasping or clamping) described above.⁵⁰ It is postulated that this technique requires less force than the more commonly done procedure previously described.⁹ A variation of this technique involves applying lateral traction to the upper humerus using a sheet looped around the upper arm.⁴⁹

FIGURE 101-7. Reduction of a posterior sternoclavicular joint dislocation. **A.** Patient positioning. **B.** An assistant applies distal in-line traction. **C.** The medial clavicle is grasped and elevated while maintaining distal traction on the extremity. **D.** An alternative technique. A towel clamp is placed around the medial clavicle. The clamp is used to elevate the medial clavicle while maintaining distal traction on the extremity.

Other less commonly performed methods for closed reduction of posterior sternoclavicular joint dislocations have been described. Reduction was achieved using 4.5 kg of lateral skin traction on the abducted arm for 30 minutes.¹¹ Reduction has also been achieved by simple forced retraction of the lateral clavicle.¹³ Reduction has been reported in a sedated patient positioned on an interscapular towel roll for 8 hours.⁵¹

ASSESSMENT

Assess the vascular integrity and neurologic function of all patients initially and following any reduction attempts. It may be prudent to confirm proper bony positioning with post-procedure imaging although studies on this topic have not been done. Additional reduction attempts may be performed if imaging shows incomplete dislocation resolution.

Anatomically correct positioning is not essential in reductions performed for neurologic or vascular compromise. The primary consideration is resolution of the neurologic or vascular compromise. The Orthopedic Surgeon can later reduce the defect that remains.

AFTERCARE

General orthopedic care principles apply. Recommend rest with activity as tolerated, local ice application, immobilization of the injured joint, and nonsteroidal anti-inflammatory drugs. Prescribe supplemental narcotic analgesics as necessary.

ANTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

The sternoclavicular joint is often unstable following reduction of anterior sternoclavicular joint dislocations and requires splinting to maintain normal anatomic relationships and allow ligamentous healing.^{1,40} This is best accomplished with a figure-of-eight splint (**Figure 112-3C**). However, many patients cannot tolerate this splint. Alternatives include a sling, a sling and swath, or a sling and Velpeau dressing (**Figures 112-3A and 112-3B**). Apply one of these immobilizers. Arrange Orthopedic Surgeon follow-up within 5 to 7 days.

POSTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

The sternoclavicular joint is usually stable following reduction. The splinting and follow-up are the same as with an anterior sternoclavicular joint dislocation.

COMPLICATIONS

ANTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

Complications of the reduction are relatively minor. The sternoclavicular joint is often unstable after reduction and may redislocate

FIGURE 101-8. An alternative technique for reducing a posterior sternoclavicular joint dislocation. (Modified from Buckerfield and Castle.⁹) **A.** Patient positioning. **B.** An assistant applies distal in-line traction (large arrow). The medial clavicle will be elevated above the sternum as traction is placed on the arm (small arrows). **C.** A posteriorly directed force is applied to the shoulder to draw the medial clavicle anteriorly and laterally into its normal anatomic position.

spontaneously. Explain this to the patient prior to reduction attempts. A “cosmetic bump” can remain even if reduction is achieved and/or maintained. Even after reductions that hold, some patients have persistent pain or joint instability requiring surgery.^{1,40-44}

POSTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

Most complications associated with posterior dislocations are from the original injury and are due to compression or injury of proximate structures. The incidence of associated injuries is commonly reported as approximately 25%.^{1,8} Deaths due to these injuries have been reported.^{8,29,43,52} Potential reduction-associated complications include pain, incomplete reduction, subclavian vessel injury, and brachial plexus injury.

Chronic posterior dislocations should be reduced in an open fashion in the Operating Room. Fibrous adhesions form between the damaged joint and deeper structures and can tear the brachial plexus if the clavicle is manipulated blindly. This particular complication has also not been documented in the literature.

A higher incidence of injury to the subclavian vessels may be seen if a towel clamp is used in the reduction. This is theoretical based on the towel clamp injuring the underlying neurovascular structures in relation to the clavicle. This particular complication has also not been documented in the literature.

The reduction of a posterior dislocation can result in an anterior subluxation or dislocation.⁵⁴ This conversion of a posterior-to-anterior dislocation should not be re-reduced since it may resolve spontaneously or require open management.

SUMMARY

Sternoclavicular joint dislocations are uncommon injuries. They are usually due to high-impact forces from motor vehicle collisions or contact sports. Anterior sternoclavicular joint dislocations are easily reduced but often do not remain reduced. However, most patients do well with persistent anterior dislocations. Posterior sternoclavicular joint dislocations are even less common. Emergency Physicians should be aware of the high incidence of associated injuries. These dislocations are usually stable after reduction.

ACKNOWLEDGEMENT

I gratefully acknowledge Eric F. Reichman, PhD, MD, as the author of this chapter in the second edition. His chapter format and content were invaluable to the development of this chapter in the third edition.

Shoulder Joint Dislocation Reduction

Damali N. Nakitende, Tina Sundaram, and Michael Gottlieb

INTRODUCTION

The shoulder joint is the most commonly dislocated of all joints.¹⁻⁵ Shoulder dislocations were depicted in Egyptian murals as early as 3000 BC.¹ Despite 5000 years of medical advancements, shoulder dislocations continue to be a major cause of Emergency Department (ED) visits. They account for more than 50% of all joint complications treated by the Emergency Physicians (EPs).²

The human shoulder is remarkable for its degree of mobility. The same anatomic features that contribute to this mobility also contribute to its instability.³ The shallow glenohumeral joint allows the shoulder to be dislocated anteriorly, posteriorly, or inferiorly. Anterior shoulder dislocations are the most common and account for 95% of all shoulder dislocations.¹⁻⁴ The overall incidence of shoulder dislocations is 17 per 100,000. There is a bimodal age distribution.^{1,4,6} It occurs most commonly in males from 20 to 30 years of age, typically related to athletics and trauma. The other large group is women from 60 to 80 years of age primarily due to falls.

ANATOMY AND PATHOPHYSIOLOGY

The shoulder or glenohumeral joint is a multiaxial ball-and-socket type of synovial joint that permits a wide range of motion. This range of motion is at the expense of stability.⁷ The shoulder has greater than 180° of motion in the sagittal and coronal planes and 180° of rotary movement.⁸ The spheroidal head of the humerus articulates with the shallow glenoid fossa of the scapula. The glenoid fossa accommodates roughly one-third of the humeral head. The bony landmarks surrounding the shoulder joint are the coracoid and acromion processes of the scapula. A loose, thin fibrous capsule encloses the glenohumeral joint. The muscular component of the shoulder is a fusion of four separate muscles (i.e., supraspinatus, infraspinatus, teres minor, and subscapularis) that together form the rotator cuff. **These muscles are torn and injured in shoulder dislocations, especially with posterior and inferior dislocations.**^{9,10}

The shoulder receives its blood supply from branches of the axillary artery (i.e., the anterior and posterior circumflex humeral arteries). Innervation of the shoulder is from branches of the suprascapular, axillary, and lateral pectoral nerves. The axillary nerve lies at the level of the humeral neck. The humeral head can be dislocated anteriorly into the quadrangular space where it may compress and damage the axillary nerve. This can result in a neurapraxia, paralysis of the deltoid muscle, and/or a sensory loss to the skin over the shoulder.

Shoulder dislocations can occur anteriorly, posteriorly, or inferiorly depending on the mechanism of injury. **Anterior shoulder dislocations are the most common and account for 95% of all dislocations (Figure 102-1).** An anterior dislocation usually results from direct or indirect forces causing abduction, extension, and external rotation of the limb. Anterior dislocations are classified as subcoracoid, subglenoid, subclavicular, or intrathoracic based on the location of the humeral head. **Subcoracoid dislocations account for 75% of all anterior shoulder dislocations (Figure 102-2A).** The dislocated humeral head can shift between the first three positions but generally remains in one anatomic location.² The injury is usually linked to athletics (e.g., spiking a volleyball or blocking a basketball shot) in younger patients. Older patients may sustain anterior shoulder dislocations from falling on an outstretched arm or from a direct blow on the posterior shoulder.⁴ The patient will present in obvious distress. They are holding the affected arm in

FIGURE 102-1. The types of anterior shoulder dislocations.

slight abduction and internal rotation. Their elbow is flexed and supported by the unaffected arm. The shoulder will have the typical “squared off” appearance with loss of the normal deltoid contour (Figure 102-2A). The humeral head may be palpable anteriorly.¹

Posterior shoulder dislocations account for 4% of all shoulder dislocations.¹⁻⁴ They are often missed, even by experienced EPs.¹¹ Delayed diagnoses have been made up to 1 year after the initial injury.¹² The mechanism of injury is usually indirect, with a combination of internal rotation, adduction, and flexion. The most common precipitating mechanism is a seizure.¹³ Other etiologies include electrocution, direct trauma, and falls.^{3,13} Direct trauma (e.g., a head-on motor vehicle collision in which the patient braces their hands against the dashboard) can result in bilateral posterior shoulder dislocations in rare instances. Posterior shoulder dislocations are classified based on the location of the humeral head into subacromial, subglenoid, or subspinous spaces. **Subacromial dislocations account for 98% of posterior shoulder dislocations.**^{2,12} The patient presents with their arm held in adduction and internal rotation (Figure 102-2B).¹⁴ The shoulder will appear flat anteriorly with the coracoid process visually prominent and palpable.¹

Inferior shoulder dislocations are the least common type.¹⁻⁴ They represent less than 0.5% of all shoulder dislocations. An inferior shoulder dislocation is also known as luxatio erecta because the dislocated extremity is extended upward. Inferior shoulder dislocations are usually sustained from indirect forces with the arm hyperabducted causing the rotator cuff to tear and the arm to rotate 180° externally.⁹ Alternatively, a direct axial force applied to the arm above the head (e.g., Olympic-style weight lifting) will drive the humeral head inferiorly.¹⁵ The patient will present with the affected arm shortened, fixed above their head, and the hand rotated as if asking a question (Figure 102-2C).^{9,16,17} The humeral head may be palpable along the lateral chest wall. Inferior shoulder dislocations are often associated with fractures.¹ The fractures can involve the acromion process, coracoid process, clavicle, greater tuberosity, humeral head, and/or glenoid rim.^{1,2,8,18} Complete disruption of the rotator cuff often occurs with inferior shoulder dislocations.^{1,2,8,18} Dislocations can cause capsular and rotator cuff tears, compression or tears of the axillary artery and its branches, and/or injury to the subclavian vein. Damage by traction and compression of the brachial plexus, suprascapular nerve, and the axillary nerve occurs at a rate of 21% to 36% because of their anatomic proximity.¹² Prompt reduction of the dislocation may alleviate compression injuries, enable a more

thorough examination, and allow a thorough evaluation of all the components of the shoulder.

Radiographs are required to classify the type of dislocation and diagnose fractures (**Figure 102-3**). Associated fractures are detected in up to 24% of anterior shoulder dislocations.³ They include fractures of the greater tuberosity, humeral head, coracoid process, acromion process, clavicle, and glenoid. Recent evidence suggests that clinically obvious dislocations without a high-energy mechanism can be reduced without prior radiographs.¹⁹⁻²⁶ There is no consensus at present to eliminate prereduction radiographs versus the current recommendation that all patients have at least two-view prereduction plain radiographs of the affected joint.^{19,27} Postreduction films may be considered to document the reduction of the joint,

to assess injury caused by the reduction technique, to document bony abnormalities (e.g., Hill-Sachs lesions and Bankart lesions), and to identify previously hidden fractures that were not visible on the initial radiographs. There is some evidence that postreduction radiographs may be unnecessary.^{24-26,28-32} Further study is required before this can be made the standard of care.

The anteroposterior (AP) view will clearly demonstrate anterior dislocations, inferior dislocations, and almost all humeral fractures (**Figure 102-3**). A Hill-Sachs deformity is an impaction fracture of the posterolateral portion of the humeral head (**Figure 102-4**). These are found in up to 50% of all anterior shoulder dislocations.² A Bankart lesion is an avulsed fragment of the glenoid labrum with contiguous bone (**Figure 102-5**).⁸ Both lesions tend to get worse

A

FIGURE 102-3. Radiographs of shoulder dislocations. **A.** Anterior dislocation. Red arrow identifies the glenoid fossa. Blue arrow identifies the humeral head. (Used from James Heilman, MD, www.commonswikimedia.org.) **B.** Posterior dislocation. (Used from Hellerhoff, www.commonswikimedia.org.)

the longer the humeral head remains dislocated and can further increase shoulder instability.

The AP view often shows a “normal” picture in patients with posterior shoulder dislocations. This accounts for the high incidence of missed dislocations (**Figure 102-3B**). Up to 50% of posterior shoulder dislocations were missed using only the AP view. The lateral view increased the diagnostic accuracy to 100%.³³ There are four features that suggest a posterior dislocation on AP films. There is the loss of the normal elliptical pattern produced by overlap of the humeral head and the posterior glenoid rim. The distance between the anterior glenoid rim and the articular surface of the humeral head will be increased. This is known as the “rim sign.” Internal rotation of the greater tuberosity gives the humerus the appearance of a “light bulb” or “ice cream cone.”^{2,4} An isolated fracture of the lesser tuberosity on the AP view is suggestive of a posterior shoulder dislocation until proven otherwise.² A lateral view (e.g., the Y-view,

FIGURE 102-4. The Hill-Sachs deformity. (Used from Hellerhoff, www.commonswikimedia.org.)

an axillary view, or an apical oblique view) will help delineate the posterior position of the humeral head behind the glenoid fossa when in doubt.^{1,34,35}

Bedside ultrasound (US) can be useful to diagnose a shoulder dislocation and verify the reduction (**Figure 102-6**).³⁶⁻⁴⁴ A high-frequency (e.g., 7 to 13 MHz) US transducer is preferred, but a lower frequency transducer can also be used if available. Place the US transducer transversely on the patient’s back just inferior to the lateral aspect of the scapular spine to obtain a posterior US.⁴³ It may be more practical to obtain an anterior or lateral US image in the supine patient.⁴⁴ The advantages of bedside US over plain radiographs include decreased time, lack of radiation, not waiting for procedural sedation to wear off before transporting the patient to the radiology suite, ability to perform US in any position, and minimal need for patient cooperation.

INDICATIONS

Shoulder dislocations are typically very painful and distressing for the patient. It does not matter if the dislocation is initial or recurrent. **All attempts should be made to reduce the joint as quickly as possible once the diagnosis is made.** Uncomplicated joint dislocations should be reduced within 20 to 30 minutes, or as soon as possible, to alleviate further injury to surrounding neurologic and vascular structures.⁴⁵ **It becomes more difficult to reduce the longer a shoulder is dislocated.**⁴⁵ **A patient with a neurologic deficit or a compromised distal pulse in the setting of a shoulder dislocation should undergo immediate reduction.**

CONTRAINDICATIONS

There are no absolute contraindications to reducing a dislocated shoulder. The patient’s airway, breathing, and circulation should be assessed and managed prior to reducing the dislocated shoulder.

A

B

FIGURE 102-5. The Bankart lesion. **A.** Plain radiograph. **B.** CT scan. (Photos used from RSatUSZ, www.commonswikimedia.org.)

Any life- or limb-threatening injuries should be managed before the shoulder reduction is attempted.

An Orthopedic Surgeon should be consulted prior to the reduction of a shoulder dislocation in patients with posterior and inferior dislocations. They are relatively rare, there is a high incidence of complications requiring operative management, associated fractures may make the reduction difficult, and there may be indications for surgical management.⁴⁶ The indications for surgical intervention in anterior shoulder dislocations include complete rotator cuff tears, fracture of the greater tuberosity with displacement of more than

A

B

FIGURE 102-6. US for an anterior shoulder dislocation. **A.** The characteristic empty space between the humeral head and glenoid fossa. **B.** Postreduction with the humeral head in close proximity to the glenoid fossa. (Photos used with permission from reference 69.)

1 cm, or fractures of the glenoid rim that are displaced more than 5 mm.² Posterior shoulder dislocations with major displacement of a fractured lesser tuberosity or an impression defect greater than 20% of the articular surface necessitate surgical intervention for open reduction.^{2,3} Open dislocations require operative management but may be reduced in the ED if there is a delay in getting the patient to the Operating Room. Surgical reduction is indicated in patients with evidence of hemorrhagic shock from a suspected axillary artery injury sustained during a shoulder dislocation.

Consult an Orthopedic Surgeon before reducing a dislocated shoulder that presents greater than 7 to 10 days after the acute

injury.^{47,48} There is a higher risk of vascular injury when an “old” dislocation is mistaken for an acute injury and subsequently reduced. The axillary artery, which is bound down by the pectoralis major muscle and anterior pericapsular scarring, becomes brittle and may not withstand the traction required to reduce an “old” dislocation. This is especially true in the elderly. A 50% rate of hemorrhage-related mortality was reported in patients who had shoulder reductions performed several weeks after the initial injury.¹⁸

Shoulder dislocations in children present unique problems. Pediatric patients whose ossification centers have not yet fused may have associated Salter-Harris fractures of the epiphyseal plate. **Consult an Orthopedic Surgeon prior to the reduction of a pediatric shoulder dislocation unless neurologic or vascular compromise is present in the affected extremity.** The same techniques for reduction can be applied to both adult and pediatric patients.⁴⁹

EQUIPMENT

■ GENERAL SUPPLIES

- Equipment and supplies for procedural sedation (Chapter 159)
- Assistants
- Sheets
- 10 to 15 pounds of weights
- Sling and swath or shoulder immobilizer
- Splinting material (e.g., plaster, fiberglass, prepackaged casting material)

■ INTRAARTICULAR ANALGESIA

- Povidone iodine or chlorhexidine solution
- 20 mL syringe
- 25 gauge, 2.5 inch needle
- Local anesthetic solution (e.g., lidocaine or bupivacaine)

■ MISCELLANEOUS

- Equipment and supplies for nitrous oxide anesthesia (Chapter 158)
- Equipment and supplies for regional anesthesia (Chapter 156)

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare of the procedure to the patient and/or their representative. Obtain an informed consent for the reduction procedure. An informed consent should be obtained for procedural sedation and/or an intraarticular injection if they are performed in addition to the reduction procedure.

Place the patient in a position of maximal comfort, usually sitting upright or at a 45° angle, with the affected extremity supported and its motion limited. Placing the patient supine or prone is difficult, painful, and often requires analgesia. The patient presenting in spinal immobilization should remain supine. If the spine cannot be cleared, shoulder reduction can be performed without changing the patient's position. Intravenous access should be obtained if indicated. Pain should be addressed quickly and aggressively.

ANALGESIA

There are several methods to control pain for patient comfort before and during the joint reduction procedure. Intravenous or intramuscular opioids should not be withheld pending prolonged radiographic studies. Commonly administered medications include morphine, hydromorphone, and fentanyl.

An alternative to intramuscular or intravenous narcotics is the intraarticular instillation of local anesthetic solution (Chapter 97).^{34,50-58} This is an effective method of analgesia for anterior shoulder dislocations and is often used to supplement procedural sedation. It can also be used as the only method of analgesia, when procedural sedation is contraindicated, or to decrease the agents used for procedural sedation. Clean the anterolateral shoulder of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the shoulder area and allow it to dry. Identify the hollow space 2 cm inferior to the lateral border of the acromion process (**Figure 102-7**). Using sterile technique, insert a 25 gauge needle perpendicular to the skin

A

B

FIGURE 102-7. Local anesthesia for a shoulder dislocation. The needle is introduced in the hollow under the lateral surface of the acromion process. **A.** Using landmarks. **B.** Using US. (Photos used with permission from reference 69.)

and into the hollow to a depth of 2 cm (Figure 102-7). Inject 10 to 20 mL of a 50:50 mixture of sterile saline and local anesthetic solution. This technique is effective in controlling muscle spasm and pain. **The book editor believes this should be performed on every dislocated shoulder before attempts at reduction.**

Alternative methods for providing analgesia include the use of nitrous oxide (Chapter 158), procedural sedation (Chapter 159), and regional nerve blocks (Chapter 156). Nitrous oxide has numerous advantages including a short onset, short duration of action, self-administration by the patient as needed, and a decreased ED length of stay.⁵⁹ Unfortunately, the use of nitrous oxide produces a quite variable analgesic response. Procedural sedation is commonly used as an aid in the reduction of a dislocated shoulder. US-guided brachial plexus blocks can provide excellent analgesia if the EP is trained in this technique.⁶⁰⁻⁶⁹ Please refer to Chapter 130 for the details of this technique.

Several sources suggest that patients with an anterior shoulder dislocation without a significant trauma history may accept some degree of discomfort as a trade-off for the prompt resolution of pain by reduction without anesthesia.⁷⁰⁻⁷² **Patient comfort should not be sacrificed for expediency.** Anterior shoulder dislocations may require procedural sedation prior to reduction, depending on the patient's level of discomfort and the reduction method chosen. Posterior and inferior shoulder dislocations always require procedural sedation prior to reduction.

ANTERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUES

The methods for treating a closed shoulder dislocation depend on overcoming muscular spasm to relocate the humeral head into the glenoid fossa. Reduction techniques are classified into traction techniques, leverage techniques, scapular manipulation, and combined techniques. A study evaluating various reduction techniques found similar success rates of 70% to 90% regardless of the technique.⁷³ Postreduction complications rates are variable.⁷³ The major considerations in deciding which technique to use are EP experience, EP familiarity with the technique, availability of time, and the presence or absence of an assistant.⁷³

HENNIPEN TECHNIQUE

The Hennipen technique was popularized at Hennipen County Medical Center and is often the preferred method to reduce anterior shoulder dislocations (Figure 102-8). This technique can be accomplished with no anesthesia or with the intraarticular instillation of local anesthetic solution. Procedural sedation is not required but may be used if the patient has severe pain and muscle spasms.

Place the patient seated, supine, or reclined 45° on a gurney (Figure 102-8A). Place the affected arm in adduction with the elbow in 90° of flexion. Support the patient's flexed elbow against their torso with the nondominant hand. Grasp the patient's forearm with the dominant hand. Slowly rotate the arm externally. **Stop the motion and wait until the spasm subsides if the pain becomes severe from rotator cuff spasm. Do not release the arm or return it to its original position.** Continue to rotate the arm externally until the humeral head reduces or the arm reaches the coronal plane (i.e., 90° of external rotation). This can take up to 10 minutes to accomplish. If the humeral head is still dislocated, slowly abduct the arm until the humeral head reduces or full abduction is obtained (Figure 102-8B).² Full abduction occurs when the patient's hand crosses over their head and touches the contralateral ear. Adduct the arm until it is against the patient's torso. Examine the shoulder. Another technique should be attempted if the humeral head is still dislocated.

The advantages of this technique include little or no patient manipulation and positioning, the relative ease of reduction, minimal equipment, the requirement of only a single person, and the ability to perform the reduction without analgesia. The success rate when performed by EPs is approximately 80%, with 36% of patients not requiring analgesia.³ The major disadvantage is that patients are too apprehensive and experience too much discomfort to relax their arms sufficiently to allow for reduction to occur. This problem can be eliminated by the intraarticular instillation of local anesthetic solution. The patient will occasionally require procedural sedation.

EXTERNAL ROTATION TECHNIQUE

This is a modified version of the Hennipen technique.⁷⁴⁻⁷⁹ The technique is identical to the Hennipen technique except that the

A

B

FIGURE 102-8. The Hennipen technique to reduce an anterior shoulder dislocation. **A.** Patient positioning and external rotation of the humerus. **B.** Abduction of the arm with the elbow flexed 90°.

procedure is terminated when the arm reaches 90° of external rotation. The step of abduction is not performed. The advantages and disadvantages are as listed for the Hennipen technique. The success rate ranges between 78% and 97%.^{74,76,78-80}

STIMSON TECHNIQUE

The Stimson technique is a safe first-line technique that uses gravity and weights to overcome muscle spasm and reduce the dislocated shoulder (**Figure 102-9**).⁸¹⁻⁸⁴ Instill intraarticular local anesthetic solution into the shoulder joint prior to attempting the reduction. Procedural sedation is usually not necessary. **The patient must be under constant observation to monitor pulse oximetry and respiratory status if procedural sedation is used because of the patient's prone positioning.**

Place the patient prone with the dislocated arm hanging over the side of the gurney (**Figure 102-9**). Place the shoulder in 90° of flexion. A pillow or folded sheets may be placed beneath the affected shoulder for patient comfort. Tie a sheet around the patient's hips and the gurney to prevent them from falling off the bed (**Figure 102-9**). Apply 3 to 5 pounds of weight to the patient's wrist or forearm. The weights can be attached by a commercially available device, hung off a padded wrist restraint, or hung off gauze wrapped circumferentially around the wrist. Raise the gurney so that the weights are suspended off the ground (**Figure 102-9**). Every few minutes, add an additional 3 to 5 pounds of weights until a total of 10 to 15 pounds is achieved. The weights will provide traction in a position of forward flexion and are usually sufficient for reduction to take place within 15 to 30 minutes.⁴ If the reduction is unsuccessful after 30 minutes, grasp the patient's forearm and twist it to gently rotate the humerus externally and then internally while the patient is prone and the arm is maintained under traction.⁸⁵ This additional maneuver will often reduce the dislocation if the weights alone are unsuccessful.

An alternative method is to have the patient grip a bucket half-filled with water. This will provide the necessary traction weight to

FIGURE 102-9. The Stimson technique to reduce an anterior shoulder dislocation. Weights are progressively added to the wrist to distract the humerus.

reduce the joint. The disadvantage of the bucket technique is that the patient must grip the bucket for a considerable length of time without releasing it.

The advantage of the Stimson technique is that it is safe and does not require the presence of an assistant. A 96% success rate has been reported with this technique.³ The disadvantage of the procedure is that the patient must be placed in a prone position that may be painful, uncomfortable, or impossible because of other injuries. There is a small risk of the patient slipping off the elevated gurney. **Apply a strap or sheet tied around the patient and the gurney to prevent this.** Procedural sedation is not recommended due to the prolonged prone positioning which may interfere with the patient's respirations.⁸⁶ Procedural sedation for 15 to 30 minutes is relatively contraindicated and difficult to maintain without potential complications.

SCAPULAR MANIPULATION TECHNIQUE

Scapular manipulation accomplishes reduction by repositioning the glenoid fossa rather than manipulating the humeral head (**Figure 102-10**).^{4,87-92} This is a popular technique due to its low complication rate and high patient satisfaction. This technique can be accomplished with no anesthesia and without the intraarticular instillation of local anesthetic solution. Procedural sedation is not required.

Place the patient prone with the dislocated extremity hanging over the side of the gurney (**Figures 102-10A and 102-10B**). Place the shoulder in 90° of flexion. A pillow or folded sheets may be placed below the affected shoulder for patient comfort. Place 5 to 15 pounds of weights suspended from the patient's wrist or in their hand. An assistant may apply downward traction on the extremity if weights are not available (**Figure 102-10B**). The weights or the assistant will provide in-line traction to the arm.

Identify the scapula and its borders. The scapular tip will "wing" laterally. Stabilize the superior portion of the scapula with one hand (**Figure 102-10A**). Place the thumb of the stabilization hand along the superolateral border of the scapula. Apply constant and firm medial and upward pressure to the inferior tip of the scapula using the other hand or thumb (**Figure 102-10B**). The thumb of the stabilizing hand can also be used to apply medially directed pressure to the tip of the scapula. Push the tip of the scapula as far medially as possible. The shoulder should reduce within 1 to 3 minutes. A small degree of dorsal displacement of the scapular tip has also been recommended.^{3,92} Slight external rotation of the humerus by an assistant while the scapula is being manipulated and the arm remains under traction may facilitate reduction (**Figure 102-10B**). This maneuver releases the superior glenohumeral ligament and presents a favorable profile of the humeral head to the glenoid fossa.^{90,92}

The scapular manipulation technique may be performed with the patient supine (**Figure 102-10C**). This is particularly helpful when other injuries or conditions preclude using the prone position. Place the affected shoulder in 90° of flexion. Instruct an assistant to grasp the forearm and apply upward traction to elevate the shoulder off the bed. Apply your hands to stabilize and manipulate the scapula as described previously.

This technique may be performed with the patient sitting (**Figure 102-10D**). This is particularly helpful when other injuries or conditions preclude using the prone or supine position. Place the affected shoulder in 90° of flexion. Instruct an assistant to grasp the forearm and apply horizontal traction. Apply your hands to stabilize and manipulate the scapula as described previously. This method is technically more difficult because the patient's torso is not stabilized and moves during the traction and scapular manipulation.^{3,90,92}

The reduction of an anterior shoulder dislocation by the scapular manipulation technique is usually quite subtle and may be missed by

FIGURE 102-10. The scapular manipulation technique to reduce an anterior shoulder dislocation. **A.** Proper hand positioning. The upper hand stabilizes the base of the scapula while the lower hand applies medial and upward pressure on the tip of the scapula (*curved arrow*). **B.** Reduction with the patient prone. Traction is applied by an assistant (*straight arrow*). Occasionally, external rotation is also required (*curved arrow*). **C.** Reduction with the patient supine. Traction is applied on the humerus to elevate the shoulder off the bed (*arrow*). **D.** Reduction with the patient sitting. Traction is applied on the humerus (*arrow*).

both the patient and the EP. The act of lying prone will be sufficient to relocate the shoulder in a few rare cases. Success rates of 79% to 90% have been reported with this technique.^{3,4,87-92} The procedure is well tolerated.^{3,4,87-92} There is a very low incidence of complications with this procedure and it can be performed without analgesia and monitoring.⁸⁷ Disadvantages include the prone position and the need for an assistant to apply traction on the arm.

TRACTION-COUNTERTRACTION TECHNIQUE

The traction-countertraction technique is commonly performed in the ED out of tradition (**Figure 102-11**). It may be used as a first-line technique or a backup for patients who have failed alternate techniques.² This technique requires anesthesia and analgesia. Instill

local anesthetic solution intraarticularly. This may be sufficient. Many patients will require procedural sedation. This technique can cause significant patient discomfort.

Place the patient supine. Pass a sheet around the chest and axilla of the affected arm (**Figure 102-11A**). Place the affected arm in 45° of abduction. Instruct an assistant to firmly grasp the loose ends of the sheet. Grasp the patient's wrist and apply slow and steady traction. Instruct the assistant to apply countertraction. The assistant and EP should be exerting equal and opposite forces. **Stop the motion and wait until the spasm subsides if the pain becomes severe from rotator cuff muscle spasm. Do not release the arm or return it to its original position.** Continue applying traction and countertraction until the shoulder reduces after the spasm subsides.

FIGURE 102-11. The traction-countertraction technique to reduce an anterior or posterior shoulder dislocation. **A.** In-line traction is applied to the affected extremity after it is abducted 45°. An assistant provides equal and opposite countertraction with a sheet. **B.** An alternative method. A sheet is looped around the flexed forearm and the EP's hips. The EP leans back (arrow) to allow their body to do the work of reduction while their hand maintains the patient's elbow in 90° of flexion. **C.** An additional assistant is applying traction 90° to the traction-countertraction axis with a sheet in the axilla. Simultaneous adduction (curved arrow) and in-line traction by the EP may aid in the reduction. **D.** The single-person technique.

Direct traction on the extended arm may result in rapid operator fatigue. This is especially true if the EP is creating most of the force of traction through contraction of their biceps (**Figure 102-11A**). A less strenuous alternative is available and may be preferred (**Figure 102-11B**). Position the patient as above. Place the elbow of the affected arm in 90° of flexion. Place a looped sheet over the proximal forearm and the EP's hips. **Do not loop the sheet around their back, as this can cause low back strain.** This method allows the EP to lean back slowly and use their body weight to supply the traction force. The EP's arms should be extended with their hands grasping the patient's distal forearm. The EP's hands should maintain the patient's forearm upright with the elbow flexed to 90° while applying traction on the forearm with the sheet (**Figure 102-11B**).

Traction may need to be applied for several minutes. The application of gentle and limited external rotation to the affected arm while under traction may speed up the reduction. Alternatively, a second assistant can apply lateral pressure (i.e., lateral traction) on the humeral head with their hands. A variation of this technique involves a second assistant with a looped sheet placed high in the patient's axilla (**Figure 102-11C**). This second assistant is used to create lateral traction at the proximal humerus that is perpendicular to the traction-countertraction axis.² The EP continues in-line traction and can simultaneously adduct the patient's arm to maneuver the humeral head back into position as lateral traction is applied (**Figure 102-11C**). The second assistant may also be used with the technique demonstrated in **Figures 102-11A or 102-11B**.

Successful reduction is noted by a lengthening of the arm, a noticeable "clunk," and/or a brief fasciculation of the deltoid muscle. Disadvantages of the traction-countertraction technique include the need for more than one person, the significant degree of force required, the prolonged time and endurance required of the EP, and the need for procedural sedation. **This technique should not be used to reduce shoulder dislocations associated with significant fractures. The force required for this technique can displace fracture fragments and necessitate an open reduction or operative management of the displaced fragments.**

A technique has been developed to use this technique with a single person (**Figure 102-11D**).⁹³ The sheet to place countertraction is tied to the gurney instead of being wrapped around the waist of an assistant. The remainder of the procedure is the same as described previously.

SNOWBIRD TECHNIQUE

The Snowbird technique was named after a ski area in Utah where this technique originated.⁹⁴ It was developed to reduce the large number of ski-related dislocations quickly while conserving time and resources. This is an effective alternative reduction technique as compared with the more traditional methods. This technique can be accomplished with no anesthesia. The intraarticular instillation of local anesthetic solution is highly recommended. Procedural sedation is usually not required for this reduction technique.

Place the patient in a seated position on a chair with a back (**Figure 102-12**). Completely adduct the affected arm. Flex the elbow to greater than 90°. Support the affected arm with the other arm or a pillow. Make a 3 foot long loop of 4 inch wide cast stockinette. Place the stockinette around the proximal forearm. Instruct the patient to sit as straight as possible. Instruct an assistant to maintain the patient in an upright position by standing adjacent to the unaffected shoulder and clasping their hands around the chest (i.e., in the axilla) of the affected shoulder (**Figure 102-12**). Place one foot in the stockinette loop and apply firm downward traction with the foot while the patient tries to keep the shoulder relaxed and the affected elbow flexed. Instruct the assistant to provide

FIGURE 102-12. The Snowbird technique to reduce an anterior shoulder dislocation. Downward traction is applied to the humerus (arrow) while the humeral head is manipulated back into the glenoid fossa.

countertraction to keep the patient from moving. The shoulder may reduce. If not, with continued downward traction on the stockinette, the EP will have both hands free to apply gentle rotation and pressure on the humeral head until the shoulder is reduced.⁹⁴

The Snowbird physicians had a 97% success rate and reduced 93% of anterior shoulder dislocations without any form of analgesia.⁹⁴ The advantages of this technique include the relative ease of setup, the rapid nature of the technique, limited use of analgesia, and limited patient positioning. Potential disadvantages include the use of an assistant and the fact that this technique was used and developed on a limited patient population (i.e., young and healthy skiers).

MILCH TECHNIQUE

Milch wrote that a fully abducted arm is in a natural and neutral position in which there is little tension on the muscles of the shoulder girdle.⁹⁵⁻⁹⁷ The technique that Milch developed relies on gentle manipulation through abduction, external rotation, and traction on the arm.^{72,95-100} The patient's affected arm moves in a gradual arc, assisted by the EP, to reduce the dislocation without extensive or forceful manipulation (**Figure 102-13**). The intraarticular instillation of local anesthetic solution is highly recommended even though this technique can be performed with no anesthesia.¹⁰¹ Procedural sedation is not usually required for this reduction technique.

Place the patient supine. Position one hand with the thumb under the dislocated humeral head (**Figure 102-13A**). Slowly abduct the affected arm 180° to an overhead position (**Figure 102-13B**). This can be accomplished by having the patient lift the affected arm. Many patients are unable to do this due to pain, muscle spasm, or

FIGURE 102-13. The Milch technique to reduce an anterior shoulder dislocation. **A.** The distal humerus is grasped with one hand while the thumb of the other hand is placed under the dislocated humeral head. **B.** The arm is abducted to 180°. **C.** In-line traction is applied to the humerus while the thumb pushes the humeral head into the glenoid fossa.

apprehension. Gently grip the elbow or wrist and slowly abduct the arm to 180° (**Figure 102-13B**). Grasp the patient's distal arm or proximal forearm with one hand once the arm is fully abducted. Apply gentle longitudinal traction with slight external rotation to

the arm (**Figure 102-13C**). The humeral head may reduce. If not, while maintaining traction with external rotation, apply upward pressure under the humeral head with the other hand to guide it into the glenoid fossa (**Figure 102-13C**).

Successful reduction is attained in 70% to 90% of the cases with no requirement for assistance, other equipment, or medications.^{72,95-100,102} Advantages of the Milch technique include its gentleness, high success rate, limited complications, and good patient tolerance.^{103,104} Disadvantages include positioning the arm in full abduction with or without analgesia, severe pain, muscle spasm, and/or apprehension. This technique can be modified slightly so that the patient can perform a self-reduction under the instruction of the EP.¹⁰⁵

ALTERNATIVE ANTERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUES

Numerous alternative and less commonly used techniques are available to reduce an anterior shoulder dislocation. Some of these are modifications of existing methods. Others are original techniques that had too many associated complications and were modified with time and experience. Some are well-known and effective techniques that have been used for many years. There is very little research regarding many of these techniques. Some of these techniques may prove to be useful in the reduction of an anterior shoulder reduction. **None of these techniques are advocated as first-line treatments for the reduction of shoulder dislocations. Their inclusion here is for the sake of completeness and does not necessarily constitute an endorsement for their use.** Only a select few of these techniques are discussed.

HIPPOCRATIC TECHNIQUE

The Hippocratic technique is the original traction-countertraction technique (**Figure 102-14**).¹⁰⁶ It is one of the oldest documented techniques to reduce a shoulder dislocation.^{2,18,82,106} This technique has the advantage that it can be performed by a single operator in any setting. **The Hippocratic technique is efficient but not recommended due to the great force required to achieve reduction.** Common complications of the technique include fractures, brachial plexus injury, vascular injury, and poor patient tolerability.^{2,8,18}

Place the patient supine (**Figure 102-14**). Grasp the wrist of the affected arm and abduct the arm 20° to 30°. Place one foot into the axilla of the affected arm. Firmly grasp the patient's wrist and apply traction to the arm while extending the foot in the axilla to provide countertraction.

FIGURE 102-14. The Hippocratic technique to reduce an anterior shoulder dislocation. Traction is applied to the arm while countertraction is applied using a foot in the axilla.

KOCHER TECHNIQUE

The Kocher technique was first recorded on an Egyptian mural dated 1200 BC.¹⁰⁷ It is another traditional method that has come into disfavor. This maneuver relies upon leverage and humeral manipulation to reduce the shoulder (**Figure 102-15**).¹⁰⁸ The humeral head is levered on the anterior glenoid while the humeral shaft is levered against the anterior thoracic wall until reduction is achieved.^{18,107,109} A substantial amount of force must be applied while adducting and externally rotating the arm to reduce the joint.

Place the patient sitting at a 45° incline or supine. Abduct the affected arm to 45° and flex the elbow to 90° (**Figure 102-15A**). Grasp the patient's distal humerus with the dominant hand and the patient's wrist with the nondominant hand (**Figure 102-15A**). Apply in-line traction to the distal humerus. Rotate the arm externally to its maximum extent while maintaining in-line traction (**Figure 102-15B**). Move the patient's elbow across their chest and to the midline while maintaining in-line traction; the elbow is held tightly against the patient's chest (**Figure 102-15C**). Internally rotate the arm while in-line traction is maintained and until the patient's hand touches their opposite shoulder (**Figure 102-15D**).

The main advantage of this method is that it is a single-person technique that has withstood the test of time. Studies have shown that the forces generated are sufficient to cause fractures of the humeral neck, spiral humeral fractures, vascular trauma, and brachial plexus injury.¹⁸

ESKIMO TECHNIQUE

The Eskimo technique uses the patient's body weight and gravity as a traction mechanism to reduce an anterior shoulder dislocation.¹¹⁰ It can be performed in the field, where access to a health care facility may be limited. Disadvantages of this technique include the strength and stamina required to lift the patient, injury due to heavy lifting, poor patient tolerability, and increased stress on the brachial plexus and axillary vessels.

Place the patient on the floor and lying on the unaffected side (**Figure 102-16**). Instruct the patient to place the affected arm tightly adducted with the elbow flexed to 45° (**Figure 102-16A**). Grasp the injured arm and slowly lift the patient 6 to 12 inches off the ground (**Figure 102-16A**) so that the patient's body weight produces enough traction to reduce the joint. This technique was initially described and reported to have a 74% success rate.¹¹⁰

Two alternatives exist. The patient can be positioned on the unaffected side with the affected arm abducted to 90° (**Figure 102-16B**). One or two people can then grasp the patient's wrist and forearm and lift the patient 6 to 12 inches off the ground (**Figure 102-16B**). Some patients cannot move to the floor. Position the patient with the unaffected side on the gurney. Stand on the gurney while an assistant holds the EP so they do not fall. This risks the EP falling off the gurney and becoming injured.

CHAIR TECHNIQUE

The chair technique is a simple method to reduce an anterior shoulder dislocation.¹¹¹⁻¹¹⁴ It is a variation of the traction-countertraction technique. Place the patient sitting sideways or backward in a chair with the affected arm draped over the back rest (**Figure 102-17**). Supinate the patient's wrist and apply downward traction while the patient attempts to stand and provide countertraction (**Figure 102-17**).

This technique has a 72% success rate.³ The advantages include the simplicity of the technique, not requiring an assistant, not needing any equipment, and not requiring analgesia. A large amount of force is required to reduce the shoulder. These forces can cause

FIGURE 102-15. The Kocher technique to reduce an anterior shoulder dislocation. **A.** The arm is abducted to 45° with the elbow flexed to 90°. In-line traction is applied to the humerus (arrow). **B.** The arm is rotated externally (curved arrow) while traction is maintained (straight arrow). **C.** The elbow is brought across the chest to the midline while the arm is still rotated externally and traction on the arm is maintained (straight arrow). **D.** Traction is maintained while the arm is rotated internally until the patient's hand touches their opposite shoulder.

injury to the brachial plexus and axillary vessels as the axilla is impinged on the back of the chair.

WRESTLING TECHNIQUE

A new technique was recently described based on optimal anatomic positioning with limited complications.¹¹⁵ Place the patient supine with the elbow of the affected shoulder flexed to 120°. Grasp the dislocated arm just above the humeral condyles and apply distal traction to the arm. Grasp the distal forearm overhanded with the opposite hand and move the hand from the condyles through the acute angle of the arm, grasping the wrist of the hand holding the forearm. The wrestling hold is now established (Figure 102-18). The patient's forearm will be used as a fulcrum. Abduct the patient's shoulder to 45° while maintaining constant traction. Externally rotate the arm in a slow, smooth motion. Move the patient's arm over their chest wall while maintaining traction and maintaining external rotation, and then rotate it internally.¹ The shoulder should subsequently reduce.

This technique has the advantages of requiring no equipment, no analgesia, and no assistants. It may be used in the field where a health care facility is not readily available. The main disadvantage is the amount of force applied to the shoulder and surrounding structures. The twisting of the forearm as a lever can displace fracture fragments or cause new fractures. This technique requires the EP to have a significant amount of upper body strength and arms long enough to accomplish the wrestling hold. It is difficult to apply the

wrestling hold if the patient has large arms. The series of movements is difficult to accomplish while always maintaining distal traction.

PNEUMATIC STRETCHER TECHNIQUE

This technique was developed to reduce a shoulder dislocation when assistants were not available or if the physician did not have the physical strength required to use other techniques.¹¹⁶ It is a modification of the traction-countertraction technique. **This technique should never be used to reduce a shoulder dislocation.** It will cause stretching and possible rupture of the brachial plexus, ligaments of the shoulder region, muscles and tendons crossing the shoulder, nerves of the upper extremity, vascular structures of the upper extremity, and injury to other joints. **Tremendous forces are applied to the extremity with this technique.**

Place the patient prone with the affected arm hanging off the gurney (Figure 102-19). Wrap a sheet around the patient's hips and the gurney to hold the patient in position. Tie the ends of the sheet into a knot or have them held by an assistant. Wrap the patient's wrist with gauze and tie it to the base or wheel of the gurney. Begin elevating the bed until the dislocation is reduced.

SPASO TECHNIQUE

The Spaso technique is a single person technique that is simple to perform.¹¹⁷⁻¹²¹ It uses minimal force and can be performed without procedural sedation. This technique is similar to the Stimson

FIGURE 102-16. The Eskimo technique to reduce an anterior shoulder dislocation. The patient is lying on the floor on the unaffected side. **A.** The patient is lifted off the ground by grasping the adducted arm. **B.** The patient is lifted off the ground by grasping the distal forearm of the affected arm.

technique, with the main difference being the patient's position.¹¹⁸ Successful rates of reduction can be seen in up to 87% of patients.¹¹⁹⁻¹²¹

Place the patient supine. Grasp the wrist of the affected arm with the dominant hand and the patient's proximal forearm with the non-dominant hand (**Figure 102-20**). Slowly flex the patient's shoulder until the arm is upright and the shoulder is flexed to 90° (**Figure 102-20**). Apply upward traction to the arm while gently

externally rotating the arm. Slowly increase the upward traction until the shoulder reduces. If reduction does not occur, use the non-dominant hand to apply externally directed pressure to the humeral head to push it into the glenoid fossa while maintaining the arm in traction and external rotation with the dominant hand. An assistant may be required to push on the humeral head while the EP uses both hands to apply upward traction.

FIGURE 102-17. The chair technique to reduce an anterior shoulder dislocation. Traction is applied to the arm as the patient attempts to stand and provide countertraction.

FIGURE 102-18. The wrestling technique to reduce an anterior shoulder dislocation. Traction and external rotation are applied to the arm after the hold is established.

FIGURE 102-19. The pneumatic stretcher technique to reduce an anterior shoulder dislocation. The gurney is raised to provide countertraction to the traction applied to the wrist that is by being tied to the base of the gurney.

OZA MANEUVER

Direct manipulation of the humeral head with simultaneous arm traction may allow for a simple reduction of the humeral head.¹²² This technique is a modification of the traction-countertraction technique. Very little information exists in the literature regarding the effectiveness of this maneuver.

Place the patient supine with the affected arm and their body against the edge of the gurney (**Figure 102-21**). Instruct an assistant to grasp the patient's wrist and slowly abduct the arm until it is at 45° to 90°. Stand between the patient's abducted wrist and their body, with your back against the patient's body. Place both thumbs against the dislocated humeral head. Wrap the fingers of both hands around the proximal humerus and interlace the fingers. Instruct the

FIGURE 102-21. The Oza maneuver to reduce an anterior shoulder dislocation. Traction is applied to the arm as the humeral head is pushed outward.

assistant to apply traction to the arm while simultaneously using the thumbs to lift and push the humeral head up and over the anterior glenoid lip and back into the glenoid fossa. Alternatively, the EP can stand outside the patient's abducted arm, wrap their fingers around the proximal humerus, and pull the humeral head back into the glenoid fossa.

BEST OF BOTH (BOB) MANEUVER

The BOB maneuver is a combination of distally applied traction and scapular manipulation.¹²³ This maneuver is quick to perform and does not use procedural sedation. It requires the patient to sit upright with their legs dangling off the gurney. This maneuver is not appropriate to use with procedural sedation, intubated patients, multitrauma patients, those who cannot sit upright, or anyone with altered mentation. The BOB maneuver can be performed with no analgesia and without the instillation of local anesthetic solution intraarticularly.

Lower the gurney as much as possible. Elevate the head of the gurney to 90°. Place the patient sitting upright on the side of the gurney with their unaffected arm against the upright head of the gurney. The patient's feet may touch the floor or dangle. Instruct the patient to "scoot over" until their unaffected shoulder and hip are tight against the head of the gurney. Kneel on the gurney facing the patient (**Figure 102-22**). Flex the elbow of the affected arm to 90°. Place one hand on the patient's proximal forearm adjacent to the antecubital fossa. Grasp the patient's wrist with the other hand. Lean down with your body weight and pull the patient's humerus downward (**Figure 102-22**). Instruct an assistant to simultaneously stand behind the patient and perform the scapular manipulation technique. The combination of traction of the humerus and scapular manipulation will allow the humeral head to relocate in the glenoid fossa.

LEGG REDUCTION MANEUVER

This maneuver is a simple technique to reduce an anteriorly dislocated shoulder.¹²⁴ It was developed and used to treat athletes in the field. Many patients may not tolerate the pain associated with this maneuver. It is not appropriate to use this technique with procedural sedation, intubated patients, multitrauma patients, those who cannot sit upright in a chair, or anyone with altered mentation. The maneuver can be performed with no analgesia and without the instillation of local anesthetic solution intraarticularly.

FIGURE 102-20. The Spaso technique to reduce an anterior shoulder dislocation. Upward traction is applied (arrow) as the arm is externally rotated (curved arrow).

FIGURE 102-22. The best of both (BOB) maneuver to reduce an anterior shoulder dislocation. Traction is applied to the humerus as the tip of the scapula is pushed medially. **A.** Superior view. **B.** Lateral view.

Place the patient sitting upright in a chair. Instruct an assistant to provide slight downward pressure on the unaffected shoulder (**Figure 102-23A**). Instruct the assistant to maintain downward pressure on the shoulder throughout the maneuver. Place one hand on the affected shoulder and apply downward pressure while abducting the patient's arm with the other hand (**Figure 102-23A**). Externally rotate the arm and flex the elbow to 90° until the patient's palm faces outward (**Figure 102-23B**). Pull the elbow and forearm posteriorly until it crosses a plane through the occiput (**Figure 102-23C**). Adduct the arm while simultaneously flexing the elbow from 90° to full flexion (**Figure 102-23D**). Internally rotate the arm until the hand touches the unaffected shoulder and the humerus relocates (**Figure 102-23E**).

CUNNINGHAM TECHNIQUE

Neil Cunningham developed a technique to simply, quickly, and painlessly reduce an anterior shoulder dislocation without the use of medications.^{125,126} His technique is based on the principle of relaxing the biceps brachii muscle with massage while the rhomboids retrovert the scapula to allow the humeral head to relocate.

Place the patient sitting upright in a chair or on a gurney (**Figure 102-24**). Stand next to the affected arm and face the patient. Fully adduct the humerus and flex the elbow to 90°. Insert one hand between the patient's forearm and their body. Grasp the patient's proximal forearm so that their hand and wrist are resting on your upper forearm (**Figure 102-24**). Instruct the patient to shrug their

FIGURE 102-23. The Legg reduction maneuver to reduce an anterior shoulder dislocation. **A.** Initial patient positioning. **B.** The affected arm is externally rotated and the elbow flexed to 90°. **C.** The arm is moved posteriorly. **D.** The arm is adducted while fully flexing the elbow. **E.** Internal rotation of the arm.

FIGURE 102-24. The Cunningham technique to reduce an anterior shoulder dislocation. Traction is applied to the humerus while the trapezius, deltoid, and biceps muscles are massaged sequentially.

shoulders superiorly and posteriorly to square-off the angle of their shoulder. Apply steady and downward pressure to the patient's forearm. With your other hand simultaneously massage the patient's trapezius, deltoid, and biceps muscles sequentially. Repeat the massage process while maintaining the downward traction and concentrating on the biceps until the shoulder reduces.

BOSS-HOLZACH-MATTER TECHNIQUE

This technique allows the patient to self-reduce an anterior shoulder dislocation.¹²⁷⁻¹³⁰ The patient can control the application of force to minimize their pain during the reduction. It is a hybrid of the traction-countertraction and scapular manipulation techniques. The EP instructs the patient through the technique. This technique is only successful in 60% of anterior shoulder dislocations. This is significantly lower than many other commonly used reduction techniques.

Place the patient supine on a gurney. Elevate the head of the gurney to 90°. Bind the patient's wrists together with an elastic or gauze bandage. Instruct the patient to flex their knee on the affected side. Instruct the patient to place their bound wrists in front of the flexed knee (**Figure 102-25**). Lower the head of the gurney completely. Instruct the patient to slowly lean back while simultaneously hyperextending their neck and shrugging their shoulders anteriorly to move the glenoid fossa anteriorly and inferiorly. The humeral head will reduce as the glenoid fossa moves toward the humeral head while traction is applied to the humerus.

FIGURE 102-25. The Boss-Holzach-Matter technique to reduce an anterior shoulder dislocation. The patient leans back to provide countertraction while the wrists are secured over the knee to provide distal traction.

FARES METHOD

This technique can reduce an anteriorly dislocated shoulder in an average of 2 to 3 minutes with the use of procedural sedation.¹³¹ The FARES method has a 78% success rate and only requires a single person to perform the reduction.

Place the patient supine with the affected arm at their side. Fully extend the elbow and place the forearm in the neutral position with the patient's thumb pointing upward. Grasp the distal forearm and hand. Apply longitudinal traction on the arm (**Figure 102-26A**). Oscillate the forearm continuously with brief (e.g., 2 to 3 cycles/second) and short range (e.g., 5 cm above and below the horizontal plane) vertical movements of the arm (**Figure 102-26A**). Slowly

FIGURE 102-26. The FARES method to reduce an anterior shoulder dislocation. **A.** Longitudinal traction is applied to the abducted arm as vertical oscillatory movements are made with the forearm. **B.** The arm is further abducted and externally rotated as longitudinal traction and vertical oscillatory movements are continued. **C.** The arm is further abducted as longitudinal traction and vertical oscillatory movements are continued until the shoulder reduces.

adduct the arm while maintaining longitudinal traction and vertical oscillatory movements (**Figure 102-26B**). Externally rotate the arm until the palm is facing upward and the arm is approximately 90° abducted. Continue to slowly abduct the arm while maintaining longitudinal traction and vertical oscillatory movements until the shoulder reduces (**Figure 102-26C**). The shoulder usually reduces at approximately 120° of abduction. Gently internally rotate the arm and adduct it until the humerus is against the chest and the forearm is resting across the chest.

GONAI'S TECHNIQUE

The GONAI'S technique is a self-reduction method that involves squatting.¹³² The word GONAI'S is an acronym for “grasp a waist-high object, opposite arm assists, nonsedated, autoreduction/autotraction, immobilize the grasped object, and squatting and stooping.” The advantages of this method include the following: self-reduction, quick reduction, the patient does not have to lie down or sit, minimal discomfort, minimal amount of force required, and the opposite hand can assist. The disadvantage is having to be able to squat.

Position the patient next to the locked gurney so it will not move (**Figure 102-27A**). Instruct the patient to grasp the waist-high gurney with the affected arm (**Figure 102-27A**). They can use the opposite arm to support the affected arm. The patient stands straight (**Figure 102-27B**). The patient applies gentle traction on the affected arm and gradually steps back (**Figure 102-27C**). The patient has stepped back and flexes their upper body forward (**Figure 102-27C**). The patient squats down and abducts the dislocated shoulder (**Figure 102-27D**). The patient squats until they have completely squatted (**Figure 102-27E**). Instruct the patient to lean forward and move a few steps backward while remaining in a squat (**Figure 102-27F**). Instruct the patient to use the opposite hand to apply pressure and push the humerus backward to reduce the dislocation (**Figure 102-27G**).

SOOL'S METHOD

Sool's method was developed to overcome muscle spasm and reduce pain.^{133,134} It is easy to perform, reduces the dislocation quickly, and has a 75% success rate. The addition of intraarticular local anesthetic would probably increase the rate of successful reduction. The disadvantages of this technique include the requirement for the patient to sit upright, severe pain limiting the lifting of the affected arm, the strength required of the EP, and the lack of sedation in the sitting patient.

The patient is placed in a sitting position with their back straightened. The EP stands in front of the patient (**Figure 102-28A**). The EP grasps the patient's elbow (**Figure 102-28A**). The patient's hand and arm are raised and angled toward the EP's shoulder. The patient raises their affected arm and hand until the angle of the arm and trunk reaches 90° (**Figures 102-28A and 102-28B**). The EP is still holding the patient's elbow. The patient's hand and arm are resting on the EP's shoulder (**Figures 102-28C and 102-28D**). Maintain hold of the patient's elbow and grasp the anterior part of the deltoid and pectoralis muscles with the other hand (**Figure 102-28D**). Slowly pull the elbow upward and out while massaging the anterior part of the deltoid and pectoralis muscles (**Figure 102-28E**). A clunk is felt as the shoulder is reduced. Instruct the patient to maintain this position.

DAVOS TECHNIQUE

The Davos technique is named after the hospital in Switzerland in which the physicians described it had worked.^{128,129,135,136} It is one of the self-reduction techniques that can be used outside the hospital. There is confusion about the name. This technique is the same as the Boss-Holzen-Matter technique discussed earlier.

POSTERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUE

An Orthopedic Surgeon should be consulted before attempting to reduce the shoulder due to the rarity of posterior shoulder dislocations, the difficulty of reduction, the high incidence of associated injuries, and the need to operate to repair the associated injuries.^{2,4,12,18,137,138} **The only exception is when the affected extremity has signs of neurologic or vascular compromise and the Orthopedic Surgeon is not immediately available to reduce the shoulder.** The patient will require intraarticular instillation of local anesthetic solution and procedural sedation for the performance of this technique.

TRACTION-COUNTERTRACTION

Place the patient supine. Perform procedural sedation. Pass a sheet around the axilla and torso of the affected arm in the same manner as in the traction-countertraction technique (**Figure 102-11A**). Grasp the distal forearm. Apply axial traction in-line with the humerus. Instruct an assistant to apply countertraction on the sheet looped around the patient's torso. The traction and countertraction should be equal in force and in opposite directions. Gently internally rotate

FIGURE 102-27. The GONAI'S technique to reduce an anterior shoulder dislocation. **A.** The patient is positioned next to the locked gurney. They grasp the waist-high gurney with the affected arm. **B.** The patient stands straight. **C.** The patient applies gentle traction on the affected arm and gradually steps back (gray arrow). The patient has stepped back and flexes their upper body forward (clear arrow). **D.** The patient squats down and abducts the dislocated shoulder. **E.** The patient squats completely. **F.** The patient leans forward (clear arrow) and moves a few steps backward (gray arrow) while remaining in a squat. **G.** The patient uses the opposite hand to apply pressure and push the humerus backward to reduce the dislocation.

FIGURE 102-28. Sool's method to reduce an anterior shoulder dislocation. **A.** The patient is placed sitting on the edge of the gurney with their back straightened. The EP stands in front of the patient. The EP grasps the patient's elbow. **B.** The patient's hand and arm are raised and angled toward the EP's shoulder. **C.** The patient raises their affected arm and hand until the angle of the arm and trunk reaches 90°. **D.** The EP holds the patient's elbow and grasps the anterior part of the deltoid and pectoralis muscles with the other hand. The EP slowly pushes the elbow upward and out while massaging the anterior part of the deltoid and pectoralis muscles. **E.** The physician feels a clunk as the shoulder is reduced.

and adduct the arm while maintaining traction. The shoulder may reduce. If not, instruct a second assistant to apply simultaneous lateral pressure on the humeral head.³ Continue to exert pressure on the humeral head to work it over the glenoid rim. The arm may need to be gently rotated externally. If this fails to reduce the shoulder, instruct a second assistant to use a sheet looped around the proximal humerus to apply lateral traction and repeat the process (**Figure 102-11C**). If the shoulder will still not reduce, this is an indication for general anesthesia and an open or closed reduction in the Operating Room.^{4,14} The shoulder joint is usually unstable and may not remain articulated once it is reduced.

An alternative to grasping the forearm is to apply a padded wrist restraint. Tie the loose ends of the restraint straps to create a loop around the EP's hips. A second alternative is to loop a sheet around the patient's flexed forearm and the EP's hips as in the traction-countertraction technique (**Figure 102-11B**). These two alternatives are preferred, as they allow the EP's body to reduce the shoulder rather than depending on biceps strength.

INFERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUE

Inferior shoulder dislocations require an Orthopedic Surgeon to be consulted before attempting closed reduction unless neurologic or vascular compromise is present in the affected extremity.

Consultation is required because of the rarity of inferior shoulder dislocations, the difficulty of reduction, the high incidence of associated injuries, and the need to operate to repair the associated injuries.^{2-4,15,138-142} The patient will require intraarticular instillation of local anesthetic solution and procedural sedation for the performance of these techniques.⁴ An inferior shoulder dislocation is usually reduced using the traction-countertraction technique.^{15,138,142,143}

TRACTION-COUNTERTRACTION

Place the patient supine. Loop a sheet over the clavicle of the affected shoulder with the loose ends of the sheet at the opposite hip (**Figure 102-29**). Stand above the patient's head and grasp the distal forearm. Apply axial traction to the arm. Instruct an assistant to apply equal countertraction on the sheet. Gently adduct the arm in a full arc from the patient's head to their side (**Figure 102-29**). The shoulder should reduce. The shoulder joint is usually unstable and may not remain articulated once reduced. In rare instances, buttonholing of the joint capsule will prevent closed reduction and require an open reduction.²

TWO-STEP MANEUVER

This maneuver consists of two steps.¹⁴⁴⁻¹⁴⁶ The first step converts an inferior shoulder dislocation into an anterior shoulder dislocation. Step two is the reduction of the anterior shoulder dislocation

FIGURE 102-29. Reduction of an inferior shoulder dislocation. Axial traction (straight arrows) is applied and maintained on the dislocated extremity while it is simultaneously hyperadducted (curved arrows).

using the external rotation technique described previously. The two-step maneuver has several advantages over using the traction-countertraction technique. This includes requiring a single person, using a single reduction attempt, possibly using less sedation, and not requiring a trip to the Operating Room for the reduction.

Place the patient supine. Stand adjacent to the affected shoulder and facing the patient's feet. Place one hand on the distal aspect of the lateral humerus and the other hand on the medial epicondyle (Figure 102-30). Use the hand on the lateral aspect of the distal humerus to push inward while simultaneously pulling the elbow outwards (Figure 102-30). This will convert the inferior dislocation into an anterior dislocation. Apply the external rotation technique to reduce the anterior dislocation (Figure 102-8A).

FIGURE 102-30. The two-step maneuver to reduce an inferior shoulder dislocation. Step one involves pushing the lateral aspect of the distal humerus while pulling on the medial condyle to convert the inferior dislocation into an anterior dislocation. Step two is the external rotation technique (Figure 102-8).

ASSESSMENT

The postprocedural care of the dislocated shoulder is as important as the initial reduction. Successful shoulder reduction can be sensed as a shift or “clunk” in the shoulder joint. Sometimes this can be a very subtle sign. The normal contour of the shoulder is restored and patients often report marked improvement in their pain. A simple test to evaluate the success of the reduced joint is to have the patient touch their contralateral ear or shoulder with the hand of the affected limb.³ The ability to do so usually signifies a relocated shoulder joint. **The patient should have a thorough examination to evaluate the extremity for vascular and/or neurologic compromise.** Any compromise requires immediate consultation with an Orthopedic Surgeon.

It is important to immobilize the shoulder to prevent further external rotation or abduction of the reduced shoulder by the patient. Place the affected extremity in a shoulder immobilizer (Figure 102-31A) or a conventional sling with a swath (Figure 102-31B).^{1,2,18,23,147-150} The shoulder should be immobilized in external rotation in a spica cast if a successful reduction is unstable (Figure 102-31C).^{3,151} Splinting the shoulder with the arm adducted and in external rotation may prevent recurrent dislocations.¹⁵²⁻¹⁶⁰ Patients should remain in this position for 3 weeks.¹⁵² A splint to hold the shoulder in external rotation can be made with splinting material, or a commercially available product may be purchased (Figure 102-31D).^{152-155,157,161}

Postreduction films are indicated after immobilization to confirm the reduction of the joint, to rule out missed fractures on the original radiographs, to rule out a fracture from the reduction procedure, and to evaluate for displacement of fracture fragments. There is some evidence suggesting that postreduction radiographs may be unnecessary, especially if atraumatic.^{28,29,35} Further study is warranted before this can be routinely recommended.

US can be used to verify the shoulder is reduced (Figure 102-6).^{162,163} Only small studies and case reports are in the literature. This technique needs to be validated before US can become standard practice and replace postreduction radiographs.

AFTERCARE

The patient will need to be observed following procedural sedation before being discharged home in the care of friends or family. It is necessary to have the patient awake, alert, oriented, and to have the pain adequately controlled before discharge. The patient should be discharged with adequate pain control and follow-up care by an Orthopedic Surgeon. Control pain during the acute inflammatory response period using oral nonsteroidal anti-inflammatory drugs supplemented with narcotics as needed for 2 to 3 days. Arrange Orthopedic follow-up within 24 hours for anterior shoulder dislocations complicated by fractures or soft tissue injuries beyond ligamentous strain. Follow-up within 5 to 7 days is generally sufficient for uncomplicated anterior shoulder reductions.

The duration of immobilization depends on the patient's age.^{2,18,73} The only large-scale prospective study of first-time anterior shoulder dislocations followed patients over a 10-year period. It found that the duration of immobilization had no effect on the incidence of recurrence. **Age was the only prognostic factor for recurrence.** Patients under 20 years of age should be immobilized for 3 weeks and then begin active range-of-motion exercises. Patients age 20 to 40 years should be immobilized for 1 to 2 weeks and begin active range-of-motion exercises 5 days after reduction. Patients older than 60 years of age should have minimal immobilization (i.e., less than 1 week) and begin active range-of-motion exercises within 72 hours after reduction to limit subsequent shoulder stiffness.^{2,18} Patients should be instructed to avoid external rotation and

FIGURE 102-31. Methods of shoulder immobilization after reduction of a dislocation. **A.** Shoulder immobilizer. **B.** Velpeau dressing. **C.** Spica cast. **D.** Immobilization in external rotation.

abduction activities (e.g., combing their hair) to avoid a recurrent dislocation.¹

Range-of-motion exercises should include dangling-arm rotation.^{2,18} While supporting the torso with the other arm, the patient makes a small circular motion with the injured arm against the force of gravity. Strengthening the subscapularis muscle by doing internal rotation against a resistance band with the elbow flexed to 90° is advocated for anterior dislocations.²

COMPLICATIONS

Complications of shoulder dislocations can occur from the initial injury, the reduction technique, or a combination of both. Complications are discussed with respect to both the initial injury and the reduction. They include fractures, displacement of fracture fragments, rotator cuff tears, vascular injury, neurologic injury, recurrence of the dislocation, hemarthroses, and the inability to reduce the shoulder.

FRACTURES

Most fractures are caused during the dislocation and rarely during the reduction procedure if the proper techniques are used.^{2,4,12,18,139} Prereduction radiographs will identify most fractures. Postreduction radiographs will identify fractures initially missed or new ones associated with the reduction. Fractures of the humerus and coracoid process are rare and almost always associated with traumatic anterior shoulder dislocations.^{1,2,12} These fractures make closed reduction very difficult and should generally be treated under general anesthesia by an Orthopedic Surgeon.

More common bony injuries include the Hill-Sachs deformity (**Figure 102-4**) and the Bankart lesion (**Figure 102-5**), both caused from the dislocation. The Hill-Sachs lesion occurs in up to 50% of shoulder dislocations.^{1,2} More significant fractures can occur during reduction in rare situations in which the humeral head is dislocated anteriorly with impaction on the glenoid rim.^{1,2,12,18} The Bankart lesion is more commonly seen in recurrent dislocations and is associated with rupture of the joint capsule but not the rotator cuff.^{1,2,12,18}

DISPLACEMENT OF FRACTURE FRAGMENTS

Obtain prereduction radiographs on all traumatic shoulder dislocations. They will identify most fractures and any associated displacement. Many of the reduction techniques use significant force and may displace a fracture fragment.¹⁶⁴ Postreduction radiographs are required to evaluate displacement of fracture fragments. The displacement of fracture fragments may make reduction difficult or impossible. They sometimes necessitate operative reduction under general anesthesia.

ROTATOR CUFF TEARS

Rotator cuff injury is most commonly seen in inferior dislocations and in patients greater than 60 years of age.^{18,140,141} Approximately 38% of shoulder dislocations will have associated rotator cuff tears at the time of injury. This injury is not typically seen as a complication of the reduction technique.^{3,18} Rotator cuff tears generally do not impede reduction, as they are often missed during the initial evaluation. One study showed that 86% of shoulder dislocations had rotator cuff tears diagnosed by arthroscopy an average of 7 months after the dislocation.^{1,4} Rotator cuff injuries complicate restoration of normal shoulder function and may require surgical correction.

VASCULAR INJURY

Vascular injuries are seen in the arteries and veins of the shoulder region in association with shoulder dislocations.^{1,12,18,139,165-167} **An evaluation for the signs of an axillary artery injury should be sought before and after any reduction attempt.** The most common vessel injured during a dislocation and forceful reduction is the axillary artery.¹⁶⁸⁻¹⁷⁰ Such an injury is usually seen in older patients who have brittle vessels that have lost some elasticity. Inferior dislocations have the highest association with vascular injuries.¹⁸ The second and third parts of the axillary artery are deep to the pectoralis major muscle and sustain the most damage.¹² Arterial injury may occur when attempting the reduction of a chronically dislocated shoulder. Arterial injuries can present with a decreased radial pulse, an axillary mass, an axillary bruit, or lateral chest wall bruising.¹ An angiogram is indicated if a vascular injury is suspected.

Direct injuries to venous vessels are atypical. The most common injury is a venous thrombosis.^{171,172} Physical signs include extremity edema and occasionally paresthesias. These signs are typically seen days after the reduction. The diagnostic test of choice for venous evaluation is a US with Doppler study.¹²

NEUROLOGIC INJURY

Neurologic injury is seen in up to 12% of all shoulder dislocations.^{12,18,139,167,173-175} **An evaluation for the signs of any neurologic injury should be sought before and after any reduction attempt.** Anterior shoulder dislocations with humeral fractures have a 45% incidence of nerve injury, with the axillary nerve being injured in up to 36% of cases.¹² Older patients tend to be more prone to nerve injury from the dislocation and the reduction techniques.¹² The techniques described that cause significant downward traction typically cause more reduction-induced neurologic injuries. Most neurologic injuries are neurapraxias and will completely resolve

within 2 to 5 months.^{18,176-179} A small percentage of axillary nerve injuries that do not resolve may require nerve grafting. Brachial plexus injuries are much more common in posterior and inferior shoulder dislocations. Injuries to the artery should raise suspicion for a brachial plexus injury because the brachial plexus surrounds the axillary artery.

DISLOCATION RECURRENCE

The incidence of recurrence is variable, age-dependent, and gender-dependent.^{149,180-182} Among patients under the age of 20 years, 90% will dislocate again, whereas only 14% of those over the age of 40 will dislocate again.^{1,183,184} Recurrences are much more common in men with a ratio of 4:1 as compared to 6:1 in women.¹⁸ Recurrent shoulder dislocations have other associated morbidities. A triad of lesions (e.g., a detached labrum and anterior capsule, a Hill-Sachs deformity, and erosion of the anterior glenoid) develops in 85% of recurrent shoulder dislocations.⁴ The methods for reduction are not different from those of a first-time shoulder dislocation. Patients who have had multiple shoulder dislocations are generally easier to reduce using nonanalgesic manipulation techniques. The orthopedic literature suggests that three shoulder dislocations in a single extremity indicate the need for surgical repair.¹⁸

HEMARTHROSIS

Blood collections in the shoulder joint are rare complications and are seen almost exclusively in traumatic shoulder dislocations associated with fractures. Patients older than 60 years of age will return to the Emergency Department within 24 to 48 hours with a tense, swollen, and painful shoulder. The shoulder joint should be aspirated (Chapter 97). Aspiration is usually sufficient to relieve pain and restore function.

INABILITY TO REDUCE

There are a few reasons for the inability to reduce a dislocated shoulder completely.^{185,186} The most common is inadequate medication and sedation to overcome muscle spasm and pain. The humeral head may be "buttonholed" through the joint capsule.¹⁸ A fracture fragment may be impinged or interposed between the humeral head and the glenoid cavity. Significant or complete disruption of ligamentous structures or soft tissue interposition will not allow the humeral head to remain in the glenoid cavity.¹⁸⁵ The inability to reduce a shoulder dislocation is an indication for reduction, open or closed, under general anesthesia in the Operating Room.¹⁸⁷

SUMMARY

Shoulder dislocations are common due to the inherent instability of the glenohumeral joint. There are three different types of dislocation, each with different mechanisms of injury and risks of associated injuries. Most dislocations are anterior shoulder dislocations. The diagnosis of a shoulder dislocation is generally uncomplicated given the history and patient presentation. The EP must be expeditious in reducing the dislocated joint once the patient is stabilized, other injuries have been ruled out, pain control has been addressed, and radiographs have been obtained to confirm the type of dislocation along with associated bony injuries.

Orthopedic Surgeons may need to be involved with the acute care of a dislocated shoulder. They should be involved in the initial reduction care of all posterior and inferior dislocations because of the rarity of these shoulder dislocations, the difficulty of reduction, the high incidence of associated injuries, and the need to operate to repair the associated injuries.

TABLE 102-1 The Techniques and Their Success Rates

	Technique	Success rate (%)	References
Anterior shoulder dislocation	Hennepin	80	3

*Small number of patients and unreliable results.

Multiple closed reduction techniques are available. They have similar success rates (Table 102-1). The method chosen, as well as the decision to use analgesia, is individualized to the EP and the patient. Certain traditional techniques (i.e., Hippocratic and Kocher) have been demonstrated to have a higher incidence of complications and should be avoided. Patients should be thoroughly evaluated before and after any closed reduction attempt for neurologic, vascular, soft tissue, or bony injury. The shoulder should be immobilized after it is reduced.

Patients should be instructed on proper aftercare and provided with adequate oral analgesia. This can be accomplished with nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics. All patients discharged from the Emergency Department should follow-up with an Orthopedic Surgeon within 1 day to 1 week, depending on the associated injuries and the patient age.

Angelique S. Kelly Campen

INTRODUCTION

The elbow is inherently subjected to dislocations because of its mechanical structure.¹ Elbow dislocations are one of the more common joint dislocations in the body, second only to dislocations of the shoulders and fingers.² Injuries to the elbow have a high potential for complications and residual disability.³ **Timely reduction is imperative to relieve pain and reduce the possibility of neurovascular sequelae.**³ Closed reduction of the elbow is unlikely to be successful if not performed promptly.⁴

The most common mechanism for a dislocation is a fall onto an extended and abducted arm.⁵ The patient usually presents with a swollen and painful arm that is held in flexion. Elbow dislocations require a significant amount of force. Up to 20% of elbow dislocations are associated with fractures.² Simple elbow dislocations have a better prognosis and are less likely to require surgical intervention than complex ones (i.e., fracture-dislocations). This chapter deals with the closed reduction of simple elbow dislocations.

One particular type of dislocation pertains primarily to the pediatric population. Subluxation of the radial head, often referred to as a "nursemaid's elbow," occurs commonly in preschool children. It is rarely seen after age 7 and represents 20% of upper extremity injuries in children.⁵ It occurs after sudden traction on the radius with an extended elbow, as when an adult pulls a child up into a standing

position by one arm. The annular ligament slips between the capitellum and the head of the radius impeding supination of the arm. The patient will present with the arm held in slight flexion and pronation, usually in not much distress, and not using the affected arm. The simple reduction of this dislocation is also addressed. Refer to Chapter 104 for a more detailed discussion of this topic.

ANATOMY AND PATHOPHYSIOLOGY

The elbow is a hinge joint comprising articulations between the humerus, the ulna, and the radius (**Figure 103-1**). The distal humerus consists of the extraarticular medial and lateral epicondyles which are diverging columns separated by the intraarticular trochlea and capitellum. The trochlea articulates with the proximal ulna. The articular surfaces of the trochlea extend from the coronoid fossa anteriorly to the olecranon fossa posteriorly. The anterior and posterior fossae provide space for the coronoid and olecranon, respectively, at the extremes of motion. The capitellum is a spherical structure that articulates with the concave radial head.

Numerous neurovascular structures cross the elbow (**Figure 103-2**). The prominent medial epicondyle protects the ulnar nerve which travels in its posterior sulcus. The radial nerve travels just anterior to the lateral epicondyle. The median nerve travels with the brachial artery through the antecubital fossa.

There are four ligamentous structures of importance in considering injuries to the elbow: the radial collateral ligament, the ulnar collateral ligament, the annular ligament, and the anterior capsule (**Figure 103-3**). The annular ligament and radial collateral ligament hold the radial head in position. The annular ligament allows the radial head to rotate under it during pronation and supination.

The relationship of the radius and ulna to the humerus is used to classify elbow dislocations into posterior, anterior, medial, lateral, and divergent (**Figure 103-4**).^{6,7} The majority of elbow dislocations are posterior in direction (**Figure 103-5**) and account for 80% to 90% of dislocations.⁷⁻⁹ The other types of elbow dislocations are uncommon.⁹ The radius and ulna are held tightly together by the annular ligament and the interosseous membrane (**Figure 103-3**). Posterior elbow dislocations result in the radius and ulna projecting posterior to the humerus (**Figures 103-4A and 103-5**). The radius and ulna may be slightly lateral or medial in posterior elbow dislocations in addition to being posteriorly displaced. This does not affect the management or prognosis. The presence of a fracture of the radial head or coronoid process may frequently render any attempt at reduction unstable and will usually require an open reduction.¹⁰

FIGURE 103-1. Bony anatomy of the elbow region. The right arm is demonstrated in these illustrations. **A.** Anterior view. **B.** Posterior view. **C.** Posterior view of the elbow in 90° of flexion. **D.** Lateral view of the elbow in 90° of flexion.

FIGURE 103-2. Major neurovascular structures that cross the elbow.

Anterior elbow dislocations occur from traction of the forearm with the elbow extended or a blow to the posterior aspect of the flexed elbow. Anterior elbow dislocations result in the radius and ulna projecting anterior to the humerus (**Figure 103-4B**). Medial (**Figure 103-4C**) and lateral (**Figure 103-4D**) dislocations are rare injuries with poorer prognoses. Divergent dislocations (**Figure 103-4E**) are rare injuries that are distinct from the other types of elbow dislocations because there is dissociation of the radius and ulna. The annular ligament and interosseous membrane must be torn for a divergent dislocation to occur.

FIGURE 103-3. Major ligamentous structures of the elbow. **A.** Lateral view. **B.** Medial view.

FIGURE 103-4. Classification of elbow dislocations. **A.** Posterior. **B.** Anterior. **C.** Lateral. **D.** Medial. **E.** Divergent.

The patient usually presents with pain and swelling of the elbow. All elbow dislocations are characterized by loss of the normal relationship of the humeral epicondyles to the tip of the olecranon (**Figure 103-5**). The bony landmarks may be identified if the patient is seen immediately after the injury. However, the swelling and hemarthrosis that develop over time make it difficult to palpate these landmarks. Posterior dislocations are further apparent by a shortening of the forearm and the elbow being fixed in flexion.

INDICATIONS

All elbow dislocations require reduction. Early reduction of a dislocation, by open or closed means, is of paramount importance if good functional results are to be obtained. Closed reduction is unlikely to be successful if attempted later than 14 days after the injury.⁴ The more promptly the reduction is attempted, the more likely it is to be successful.

The vascular status of the extremity also dictates the need for emergent relocation. **Emergent and immediate relocation is necessary when there is neurologic or vascular compromise of the distal extremity.** Relocation can await titration of sedation and analgesia when the extremity is neurovascularly intact.

CONTRAINDICATIONS

There are no absolute contraindications to the closed reduction of an elbow dislocation. A relative contraindication to the procedure is when there is uncertainty, before radiographic evaluation, regarding whether the injury is a dislocation or a fracture. Closed reduction is not indicated if there is an interposed osteochondral fragment preventing concentric reduction or when there is a concomitant displaced fracture of the radial head or neck. Elbows that have been dislocated for a prolonged period of time may have closed reduction attempted but will most likely require an open procedure.

EQUIPMENT

- Towel or sheet to aid in applying traction
- Splinting materials
- Weight (sandbag, bucket with water, or any other weight)
- Procedural sedation supplies (Chapter 159)

PATIENT PREPARATION

Explain the risks, benefits, and potential complications to the patient and/or their representative. The postprocedural care should also be discussed. Obtain an informed consent for the reduction procedure.

Carefully assess and document the preprocedural neurologic (median, radial, and ulnar nerves) and vascular (brachial, radial, and ulnar arteries) status of the extremity. Splint and/or sling the affected extremity until radiographs are obtained and a closed reduction can be performed. Obtain anteroposterior and lateral radiographs to confirm the diagnosis of an elbow dislocation. Oblique views may be helpful to further define the relationship between the distal humerus, radius, and ulna. **The only case for which a preprocedure radiograph is not indicated is when neurologic or vascular compromise exists in the distal extremity and an expeditious reduction is required.**

Closed reduction of elbow dislocations requires adequate analgesia and muscle relaxation. In most cases, procedural sedation is useful.^{5,7} Regional anesthesia (axillary nerve or Bier blocks) is useful if procedural sedation is contraindicated.¹¹ Refer to Chapters 156 and 157 for details regarding regional anesthesia of the upper extremity. General anesthesia with fluoroscopy is rarely necessary unless the dislocation is associated with an undisplaced fracture of the radial head or neck.

TECHNIQUES

POSTERIOR ELBOW DISLOCATION REDUCTION TECHNIQUES

The goal of closed reduction is to distract the radius and ulna, allowing them to relocate. **The preferred technique that provides the least complications is a modification of the Stimson technique used for shoulder dislocations.**¹² Place the patient prone with the affected arm hanging off the gurney (**Figure 103-6**). Place padding anteriorly in front of the arm and shoulder so that the arm does not drag along the side of the gurney. **Care must be taken that the patient does not fall from the gurney.** Tie a sheet circumferentially around the patient's hips and the gurney. **Ensure that the patient does not have any respiratory difficulty while in the prone position.** Suspend a weight from the patient's wrist to apply traction to the arm (**Figure 103-6**). The weight should be approximately 5 pounds and may go up to 15 pounds, depending on the patient's musculature and weight. Allow the arm to dangle over the edge of the gurney for 10 minutes. If the elbow dislocation will not reduce, attempt the traction-countertraction technique.

The traction-countertraction technique can be performed but is not the optimal approach. Place the patient's arm in slight flexion. Grasp the patient's mid-humerus with the nondominant hand

FIGURE 103-6. The modified Stimson technique for reducing posterior elbow dislocations.

A

B

FIGURE 103-7. The traction-countertraction technique to reduce a posterior elbow dislocation. **A.** The one-person technique. The physician stabilizes the humerus with one hand and distracts the forearm with the other hand. **B.** The two-person technique. The assistant stabilizes the humerus and provides countertraction while the physician applies traction to the forearm.

and the patient's wrist with the dominant hand (**Figure 103-7A**). Alternatively, an assistant can grasp the humerus while the physician uses both hands to grasp the patient's wrist (**Figure 103-7B**). Stabilize the patient's humerus. Apply steady and constant traction to the patient's wrist to distract the coronoid process and allow it to slip past the humerus and back into anatomic position. The application of downward pressure on the proximal forearm can help to disengage the coronoid process from the olecranon fossa and ease the reduction.

MEDIAL AND LATERAL ELBOW DISLOCATION REDUCTION TECHNIQUE

Medial and lateral dislocations of the elbow are extraordinarily uncommon. They are usually associated with a posterior elbow dislocation. These dislocations can be reduced in a similar manner using the traction-countertraction technique used for posterior elbow dislocations. For lateral dislocations, apply traction to the patient's wrist with one hand while using your other hand to guide the proximal ulna downward, then medially, and finally backward. For medial dislocations, apply traction to the patient's wrist with one hand while using your other hand to guide the proximal ulna downward then laterally.

Emergency Physicians should not reduce a medial or lateral elbow dislocation. They are uncommon, may be associated with neurovascular complications, have severe ligamentous tears, and should be reduced by an Orthopedic Surgeon. **The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.**

ANTERIOR ELBOW DISLOCATION REDUCTION TECHNIQUE

Anterior elbow dislocations are uncommon. They are often associated with intimal injuries to the brachial artery being stretched during the injury.

Anterior elbow dislocations should be reduced by an Orthopedic Surgeon for the same reasons as a medial or lateral elbow dislocation. **The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.**

DIVERGENT ELBOW DISLOCATION REDUCTION TECHNIQUE

Fortunately, divergent dislocations are exceedingly rare. They are commonly associated with severe articular damage, interosseous ligamentous tears, neurologic injuries, and vascular injuries. The reduction technique is complex; the elbow is reduced as a two-part dislocation and often requires surgical fixation to be stabilized. Simple traction can be applied to relieve stress on the neurovascular structures but will not reduce the dislocation due to the instability of the joint.

Divergent elbow dislocations should be reduced by an Orthopedic Surgeon in the Operating Room. **The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.**

RADIAL HEAD SUBLUXATION REDUCTION

This condition is also referred to as a "nursemaid's elbow." Reduction of a radial head subluxation is a maneuver involving supination or hyperpronation flexion of the affected forearm. The forearm is quickly supination or hyperpronation the elbow flexed completely in one smooth motion. A pop or click is sometimes heard or felt by the Emergency Physician as the subluxation is reduced. Most patients are asymptomatic within 5 to 10 minutes and 90% within 30 minutes.¹³ The Emergency Physician should leave the room for 5 to 10 minutes after the procedure. Ask the parents to distract the child to see if they begin to move the arm. A fearful child will often not use a successfully reduced arm in fear of pain. Place an object (e.g., car keys, a popsicle, a toy, or another object the child may want) within grasp of the reduced extremity to encourage the child to use the extremity. Refer to Chapter 104 for the complete details regarding the reduction of a radial head subluxation.

ASSESSMENT

After a reduction, gently move the joint through the entire range of motion to ensure smooth movement and proper joint reduction. This also tests for joint stability and whether or not the joint will easily redislocate. The joint may need to be repaired operatively if it dislocates during this examination. **The neurovascular status of the extremity must again be evaluated and documented.** The integrity

FIGURE 103-8. Postreduction radiograph demonstrating a fracture of the coronoid process.

of the median, ulnar, and radial nerves as well as the brachial artery and its distal branches must be evaluated and documented. All reductions except radial head subluxations should have postprocedural radiographs to ensure proper bony alignment and the lack of a fracture (**Figure 103-8**). If full and smooth passive range of motion is not possible, which is especially common in children, postreduction radiographs should be examined for entrapment of the medial epicondyle.

AFTERCARE

Place the reduced extremity in a posterior long arm splint, from the mid-humerus to the base of the fingers, with the elbow in 90° of flexion. **Do not apply a circumferential cast due to the subsequent swelling and edema.** Suspend the arm with a sling to aid in elevating the extremity.¹⁴ The patient should be carefully observed for 12 to 36 hours for vascular impairment. Instruct the patient to return to the Emergency Department if they develop weakness, numbness, paresthesias, cold fingers, or cyanotic fingers. The patient should be admitted for observation if there is any question of neurovascular compromise. Gentle range-of-motion exercises can be started as early as 3 to 5 days after reduction if the elbow is stable.¹⁴⁻¹⁸ Schedule a follow-up with an Orthopedic Surgeon 3 to 4 days after reduction to test for joint stability. Prescribe nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics to control pain.

No immobilization is necessary for a radial head subluxation that is reduced. Immobilization in a sling with follow-up by an Orthopedic Surgeon is recommended only for recurrent radial head subluxations.

COMPLICATIONS

Several serious complications exist with simple elbow dislocations.^{19,20} The most serious and first to happen are ischemic complications. Damage to and obstruction of the brachial artery can occur with any of the elbow dislocations. Brachial artery injury occurs in 5% to 13% of patients with an elbow dislocation.²¹ It is a serious complication that can occur even without an associated fracture.²¹ **The presence of a distal pulse is not proof that there is no vascular injury.** Collateral circulation around the elbow can result in a distal pulse despite a complete brachial artery laceration or occlusion.²² Signs of an arterial injury include cyanosis, an expanding hematoma, pallor, pulselessness, and severe pain. Any suspicion of a brachial artery injury necessitates prompt angiography.^{22,23}

The second serious complication resulting from an elbow dislocation is nerve injury from traction or entrapment. Loss of median nerve function after reduction should prompt an immediate

consultation with an Orthopedic Surgeon. The ulnar nerve is most commonly injured.^{24,25} It is seen in 8% to 20% of patients with posterior elbow dislocations.²⁴

Fractures commonly occur with elbow dislocations. **Radiographs should always be obtained before and after any attempt at reduction. The only exception to obtaining prereduction radiographs is if the extremity has signs of distal neurovascular compromise and obtaining radiographs will delay the reduction.** A fractured coronoid process can sometimes become entrapped in the joint requiring an open reduction. Fractures of the coronoid process are commonly associated injuries and will usually come into near-normal opposition once reduction occurs (**Figure 103-8**). Large fragments that are displaced may require operative fixation.

Late complications of simple elbow dislocations include ectopic ossification, occult distal radioulnar posttraumatic stiffness, posterolateral joint instability, and residual pain.^{16,26}

SUMMARY

Elbow dislocations are the second most common large joint dislocations that occur in adults. The majority of dislocations are posterior elbow dislocations, although the radius and ulna can dislocate into just about any other position. Relocation involves distracting the forearm while stabilizing the humerus and putting pressure counter to the direction of the dislocation. It is not uncommon to have an associated fracture, so radiographic studies are imperative. The neurovascular status of the extremity must be carefully monitored and documented both before and after any attempts at reduction. Splint the elbow in flexion after reduction. Follow-up with an Orthopedic Surgeon and early range-of-motion exercises are recommended to ensure proper joint function.

Radial Head Subluxation (Nursemaid's Elbow) Reduction

Mark P. Kling

INTRODUCTION

Subluxation of the radial head is one of the most common pediatric orthopedic injuries. It is also known as nursemaid's elbow and a pulled elbow. This can occur in children whose age ranges from less than 6 months to the preteens. Most radial head subluxations occur between 1 and 3 years of age.^{1,2} It is a rare injury before 1 year of age and after 8 years of age. The basic cause is a pulling of the child's arm even though the exact cause varies.^{3,4} The injury is limited to small children because the radial head is less bulbous than in older children, adolescents, and adults making it easier to become subluxed. Fortunately, it can be easily reduced in the Emergency Department.⁵

ANATOMY AND PATHOPHYSIOLOGY

The classic mechanism involves axial or longitudinal traction on an extended elbow with the forearm pronated. This often occurs while someone is holding onto the child by the hand or wrist. The child is then pulled or falls while being held and is suspended by the arm. The subluxation is seen more often in the left arm than the right.⁶ This is due to more people being right-handed and holding the child's left hand or wrist while walking. It is not uncommon, however, for the child to present with a history of a fall or rolling over in bed.¹

This orthopedic injury involves the region of the elbow (Figure 104-1). The annular ligament is a thick band that wraps around the upper radial neck and radial head (Figure 104-1A). It guides the radial head as the forearm moves through pronation and supination. The injury causes the radial head to become partially dislocated from its articulation with the ulna and the capitellum of the humerus while the forearm is in a pronated state. The annular ligament then slips proximally and its lateral end becomes entrapped between the radial head and the

FIGURE 104-1. Anatomy of the elbow region. **A.** Normal anatomy. **B.** A radial head subluxation. Note the entrapped annular ligament.

capitellum (Figure 104-1B). The forearm becomes locked in pronation due to the entrapped annular ligament. This condition is painless when the forearm is held in pronation. Supination of the forearm causes pain so the child holds the extremity in pronation. The act of supination would also spontaneously return the annular ligament to its anatomic position and reduce the subluxation.

Children will present in no apparent distress.⁷ They are usually resting comfortably and have some reservation in using the affected extremity. The arm will be held with slight flexion of the elbow and pronation of the forearm (Figure 104-2A). The child may point to an area of pain, but this is not often the case. A child may be much more comfortable with the parent examining and questioning areas of tenderness as opposed to the unknown and sometimes intimidating Emergency Physician.

Radiographs are not required unless other trauma or diagnoses are suspected. The child often returns from the radiology suite, if radiographs are ordered, using the affected extremity. Radial head subluxations often reduce spontaneously during positioning for radiographs.

Bedside ultrasound can be used to quickly exclude other diagnoses.⁸⁻¹⁰ Ultrasound is accurate, easy to perform, quick, and uses no ionizing radiation. The ultrasound can be used to see the annular ligament is displaced from its normal position around the proximal radial head.⁸ The normal posterior fat pad rules out other bony pathology.⁹ A "hook sign" may be seen on ultrasound.¹⁰ This is when the supinator muscle is pulled into the joint space giving the appearance of a "hook" over the area of the radial head.

INDICATIONS

Any child presenting with the inability to utilize the partially flexed elbow, the forearm pronated and adducted, and a mechanism for a radial head subluxation should be reduced. Many Emergency Physicians may be hesitant to repeat the procedure multiple times if a child was not using the arm normally within 15 to 30 minutes after a clinically successful reduction. A decision to repeat the reduction should be considered if the radiographs appear normal and a repeat history and physical examination are consistent with the original diagnosis.

CONTRAINDICATIONS

The presence of edema, ecchymoses, tenderness other than over the radial head, suspicion of a fracture, or a mechanism of injury not consistent with a radial head subluxation should first be

FIGURE 104-2. A child with a radial head subluxation. **A.** The subluxed left forearm is held flexed, pronated, and adducted. **B.** Reduction technique. **C.** The forearm is freely mobile after reduction with normal extension and abduction.

evaluated radiographically.¹¹ **The presence of any distal neurologic or vascular compromise excludes the diagnosis of a radial head subluxation.**

EQUIPMENT

No equipment is required for the reduction of a radial head subluxation.

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare of the procedure to the child and their representative. Obtain a signed consent to perform the reduction. Place the patient sitting in the parent's lap or supine on an examination table or gurney. No pre-medication is required.

TECHNIQUES

SUPINATION AND FLEXION

Place one hand on the child's elbow with the thumb over the radial head (**Figure 104-3A**). This will aid in palpation of the traditional "click" of reduction. Gently grasp the child's wrist with the other hand (**Figure 104-3A**). Perform the following maneuvers in one smooth motion to reduce the subluxation. Apply distal traction while supinating the forearm (**Figure 104-3B**) followed

by flexion of the elbow (**Figure 104-3C**). A click may be felt as the radial head is reduced.^{1,12} If not, flex the forearm until the hand is upright. Other methods of reduction are often compared to this method.^{13,14}

HYPERPRONATION

Some feel that hyperpronation causes less pain to the child and is more successful than the supination technique.¹⁴⁻²³ This is because the arm is already being held in pronation and the additional pronation (i.e., hyperpronation) requires less force and motion than the supination technique.^{19,20}

Position the patient as described above. There are two variations on this technique. The first holds the child's elbow at 90° of flexion and hyperpronates the forearm without any additional flexion at the elbow (**Figure 104-4**).¹⁴ The second holds the child's elbow at 90° of flexion and hyperpronates the forearm while simultaneously fully flexing the elbow (**Figure 104-5**).¹⁵ Both hyperpronation techniques can successfully reduce a radial head subluxation.

ASSESSMENT

Allow 5 to 15 minutes to pass and return for a repeat examination. Children may cry at the end of the procedure but will generally only do so for a moment. As the child feels more comfortable, they will proceed to use the arm (**Figure 104-2C**). This freedom of use can be accelerated by the caregiver or physician stimulating the patient

FIGURE 104-3. Reduction of a radial head subluxation using supination and flexion. **A.** Positioning of the physician's hands. **B.** Distal traction is applied (straight arrow) while supinating the forearm (curved arrow). **C.** The forearm is maximally flexed.

to use the arm with an incentive (e.g., by offering candy, a pen, or a popsicle for the child to grab).

The child should have uninhibited use of the forearm within 30 minutes. **Reconsider the diagnosis if the child is not using the**

extremity. Consider radiography or ultrasonography of the affected extremity. Alternative diagnoses include clavicular fractures, distal humeral fractures, osteomyelitis, radial head fractures, septic arthritis, stress fractures, and Monteggia fractures. Reevaluate the elbow joint for signs of trauma. Obtain plain radiographs if not done previously or consider ultrasound for evaluation and reevaluation. Full recovery may take 24 to 48 hours if the reduction is delayed for more than 8 hours from the time of injury.

AFTERCARE

Radiographs, immobilization, splinting, analgesics, and orthopedic follow-up are not necessary if the subluxation is reduced and the child is using their arm. Educate the caregiver regarding the mechanism of injury and prevention of future subluxations.

Phone consultation with an Orthopedic Surgeon is recommended if the reduction is unsuccessful. It is not unusual to have a spontaneous reduction on repeat examination and follow-up. Immobilize the arm until the child is evaluated by an Orthopedic Surgeon. Immobilization will aid in pain relief. Consider the use of nonsteroidal anti-inflammatory drugs.

COMPLICATIONS

There are no complications associated with the reduction of a radial head subluxation. Rarely, the subluxed radial head will not reduce.²⁴ This is due to buttonholing of the radial head through the annular ligament or the brachialis tendon. Consult an Orthopedic Surgeon in these cases.

FIGURE 104-4. Reduction of a radial head subluxation using hyperpronation. **A.** Positioning of the physician's hands. **B.** Hyperpronation of the forearm.

FIGURE 104-5. Reduction of a radial head subluxation using hyperpronation and flexion. **A.** Positioning of the physician's hands. **B.** Hyperpronation of the forearm. **C.** Flexion of the hyperpronated forearm.

SUMMARY

A radial head subluxation is one of the more common orthopedic injuries of childhood. Children present with the inability to use the affected upper extremity. They hold the forearm flexed, pronated, and adducted. The reduction technique is quick and simple. Some more recent reviews suggest more effective and less painful results with hyperpronation techniques versus the supination method. It is important to educate the caregivers regarding the mechanism of injury and prevention of future subluxations.

Carpometacarpal Dislocation Reduction

Rene Pineda Carizey and Priya Perumalsamy

INTRODUCTION

The hand is frequently injured. Carpometacarpal (CMC) dislocations are an uncommon injury, composing less than 1% of all hand and wrist injuries.^{1,2} The mechanism usually occurs during hyperextension from high-velocity blunt trauma, mainly punching or falling.² The most commonly involved joints are the fourth and fifth CMC joints. Most injuries are dorsal dislocations, with volar dislocations being less common. These dislocations are usually seen in adults.

Missed diagnosis of a CMC dislocation can result in chronic pain and decreased function of the affected hand. Up to 87% of patients with CMC injuries will return to full daily activities with negligible pain if they receive appropriate management.³ The method of optimal treatment is still being debated. CMC dislocations are intrinsically unstable and usually require a Hand Surgeon evaluation for surgical fixation with percutaneous pinning, plates, or screw placement after closed or open reduction. There have been rare cases of closed reduction with conservative immobilization for CMC dislocations without associated fracture.⁴⁻⁸

ANATOMY AND PATHOPHYSIOLOGY

There are numerous bones in the hand and wrist (**Figure 105-1**). The CMC joints of the hand are gliding-type joints (i.e., arthrodial diarthrosis). The bases of the metacarpals articulate with the distal row of the carpal bones and with each other using an interlocking mechanism (**Figure 105-1**). Stability at the CMC joints is provided by four ligaments (i.e., the dorsal and palmar metacarpal ligaments and the dorsal and palmar interosseous ligaments). Intermetacarpal ligaments, wrist extensor ligaments, and wrist flexor ligaments that insert at the bases of the second, third, and fifth metacarpals further reinforce and stabilize the joints.⁹ Strong anterior joint capsules often result in dorsal dislocations. The thumb and fifth finger have a wide range of motion. The CMC joints of the ring and little

FIGURE 105-1. The hand and wrist bones. (Used with permission from Hand Specialists of TX.)

finger are relatively more mobile than the rest of the CMC joints. This makes them more susceptible to dislocation injury. The ulnar nerve passes adjacent to the hook of the hamate and just volar to the fifth CMC joint. Dislocation of the fourth or fifth CMC joint can cause traumatic nerve injury. Monitoring for a compartment syndrome (Chapter 93) is essential as there are 10 separate osteofascial compartments in the hand. These compartments are accessible for surgical release (Chapter 94).

CMC dislocations are rare.^{1,2} The thumb CMC joint is rarely dislocated. It usually results from an axial load with flexion of the thumb metacarpal resulting in a dorsal dislocation. A dislocation commonly occurs in association with a fracture. Closed reduction is usually unstable and requires operative stabilization. CMC dislocation of fingers 2 through 5 is also uncommon. It usually affects the fifth CMC joint. A dislocation commonly occurs in association with a fracture. Closed reduction is usually unstable and requires operative stabilization.

DIAGNOSTICS

Tenderness, swelling, and deformity of the proximal hand are signs of CMC dislocations (**Figure 105-2**).¹⁰ There may be a raised deformity of the dorsal hand with a palmar depression from a dorsal dislocation of the metacarpal base. The proximal metacarpals are palpable. A dorsal depression will be seen with a palpable palmar mass from a volar dislocation. Impaired hand function with decreased motion and strength are usual findings.^{11,12} Comparison between the two hands will most likely show asymmetry. Extensive soft tissue swelling may obscure some or all the findings.

Conventional radiographs remain the first-line imaging modality in the acute posttraumatic setting. This can be overwhelming given the complexity of the hand anatomy. CMC dislocations are frequently missed on routine plain radiographs.^{5,13,14} Up to 70% of CMC dislocations are missed or misdiagnosed.¹⁴ **Obtain a complete set of hand radiographs (i.e., posteroanterior [PA], oblique, and true lateral) if high clinical suspicion exists of injury and the mechanism of injury is associated with pain or deformity of the hand.** Basic radiographs allow examination of the CMC joints and intercarpal joints (**Figures 105-3 to 105-6**).^{15,16}

Recognition of common radiographic findings can prevent delays in diagnosis and treatment. PA and lateral views provide visualization of the second through fifth CMC joints. The 30° internal oblique view helps to isolate the fourth and fifth CMC joints, whereas the 30° external oblique view is useful in evaluating the second and third CMC joints.^{12,17} **The apposing joint surfaces should be parallel with a uniform 1 to 2 mm joint space. Overlap of the normally parallel joint surfaces suggests a subluxation or dislocation if the wrist is in a neutral position.**⁵ A cortical rim should be

FIGURE 105-2. The hand deformity immediately after trauma. (Used with permission from reference 10.)

FIGURE 105-5. A lateral radiograph of a fourth and fifth finger CMC dislocation.

seen at apposing margins. Blurring of the cortical rim can be a sign of abnormal angulation of the CMC bones.

A break in the parallel M-line made by following the distal edges of the trapezoid, capitate, hamate, and the bases of the second through first metacarpals indicates an abnormality in the

CMC joint (**Figure 105-7**).^{11,17} It is also termed the metacarpal cascade line technique. The metacarpal cascade line technique is one method in viewing PA radiographs to help diagnose CMC dislocations. It is more sensitive in diagnosing volar CMC dislocations when compared to other radiograph evaluation techniques.

FIGURE 105-4. A PA radiograph of a fifth finger CMC dislocation. (Used with permission from reference 16.)

FIGURE 105-6. A lateral radiograph of a second and third finger CMC dislocation.

FIGURE 105-7. The PA radiograph metacarpal cascade line technique. **A.** Normal convergence. **B.** Abnormal convergence seen in a dislocation. (Used with permission from reference 18.)

Superimpose lines over the central longitudinal axis of each metacarpal on the PA radiograph.¹⁸ The lines will converge to a common point approximately 2 cm proximal to the distal radius articular surface when the hand is in neutral position (**Figure 105-7A**). A divergent metacarpal cascade line(s) indicates a CMC abnormality (**Figure 105-7B**). Fractures of the metacarpal base or distal carpal bones should heighten suspicion for an associated CMC dislocation. The lateral view can show soft tissue swelling, a shortening of the longitudinal axis, and the direction of dislocation (**Figures 105-4 and 105-5**).^{11,17}

Zigzag lines can be drawn between the articular surfaces of the distal row of carpal bones and the metacarpal bases (**Figure 105-8**).^{19,20} These zigzag lines represent the hand bone arches. The zigzag lines are normally parallel to each other throughout the CMC joints (**Figure 105-8A**). Disruption of the parallel lines signifies a dislocation (**Figure 105-8B**).

Computed tomography (CT) and magnetic resonance imaging (MRI) have traditionally been second-line imaging modalities. Evidence suggests conventional radiograph has limited sensitivity in posttraumatic injury. MRI has the added advantage of detecting

FIGURE 105-8. The zigzag line. **A.** Schematic. (Used with permission from reference 19.) **B.** A radiograph of a dislocation. (Used with permission from reference 20.)

ligamentous injury in the absence of bone damage. **A hand injury with clinical symptoms suggestive of a CMC subluxation or dislocation with nonspecific or negative radiographic findings is an indication for CT or MRI.**^{12,17}

INDICATIONS

Management of these injuries includes prompt reduction of the CMC joint.⁵ The goal is a pain-free hand with minimal disability.^{5,7,12,15,21} Reduce any dislocation with neurologic or vascular compromise while avoiding additional trauma.

CONTRAINDICATIONS

Contraindications to closed reduction include displaced avulsion fractures, multiple dislocations or fractures, neurologic injury, overlying open wounds, significant intraarticular damage, and vascular injury. These are indications for emergent evaluation and treatment by a Hand Surgeon.¹² Chronic dislocations will require capsulorrhaphy, K-wire fixation, and/or ligament reconstruction.¹⁵ The inability to achieve adequate anesthesia will prevent closed reduction.²² Reduction with fixation may be more appropriate due to the unstable nature of the joint after closed reduction and risk of chronic posttraumatic disability.^{1,12,21,23}

EQUIPMENT

- Local anesthetic solution
- Regional nerve block supplies (Chapter 156)
- Procedural analgesia and sedation supplies (Chapter 159 for details)
- Finger trap (**Figure 105-9**)

FIGURE 105-9. A hand suspended in the finger trap with a counterweight on the arm for traction. (Courtesy of Instrument Specialists Inc., Boerne, TX.)

- Splinting material, fiberglass or plaster
- Elastic bandages (e.g., Ace wrap)
- Sling

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Obtain an additional signed consent for any anesthesia or sedation used for the reduction procedure. Perform a “time out” before the procedure to verify that the patient is correct, the site is correct, and the procedure being performed is correct. Reconcile all medications and allergies. Remove all jewelry or potentially constricting objects from the affected hand or wrist.

Prepare the patient. Position the patient in a position of comfort with the head of the bed at 45°. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure if sedation is used. Clean any dirt or debris from the skin. Apply povidone iodine or chlorhexidine solution to the skin surface and allow it to dry. Perform the local injection, regional anesthesia (Chapter 156), or procedural sedation (Chapter 159). Apply the finger trap (**Figure 105-9**).

TECHNIQUES

The closed reduction technique consists mainly of longitudinal traction with direct pressure at the base of the affected metacarpal.

CMC DISLOCATION OF JOINTS 2 TO 5

These dislocation usually require some form of anesthesia for the reduction. Apply traction using the finger trap and a weight (**Figure 105-9**). This unlocks the metatarsal bases from the proximal row of carpals and stretches the ligaments. Apply simultaneous flexion and longitudinal directed pressure on the base of the metacarpals. The dislocated metacarpal(s) should return to their normal position. Obtain a radiograph to confirm the reduction.

CMC JOINT OF THE THUMB DISLOCATION

The CMC joint of the thumb reduces easier than the other fingers. The dislocation is usually dorsal. The reduction is unstable and may sublux. Apply traction using the finger trap and a weight (**Figure 105-9**). This unlocks the thumb metatarsal base from the proximal carpal bone and stretches the ligaments. Apply simultaneous flexion and longitudinal directed pressure on the base of the metacarpal. The dislocated metacarpal should return to its normal position. Obtain a radiograph to confirm the reduction.

ALTERNATIVE TECHNIQUES

There is no definitive method of treatment of a CMC dislocation in the Emergency Department. Closed reduction may be attempted, but there is a higher risk of redislocation.^{1,12} Closed reduction with percutaneous pinning and open reduction with internal fixation are appropriate management options.²³ An early and stable anatomic reduction will produce faster mobilization and decrease posttraumatic disability.^{1,4}

ASSESSMENT

Assess the neurologic and vascular status of the hand, joint stability, and passive range of motion to ensure successful reduction.^{5,24} **It is important to evaluate the median, radial, and ulnar nerves.**

These nerves are susceptible to damage from the deformity, edema, hematoma formation, or the initial injury.²³

AFTERCARE

The urgency of Hand Surgeon evaluation is dependent on the patient's clinical status and the success of the closed reduction. Apply a thumb spica splint (Chapter 113) after closed reduction of the first CMC joint.²⁵ Apply a dorsal-volar splint (Chapter 113) to immobilize the second through fifth CMC joints after closed reduction. Early follow-up with a Hand Surgeon after reduction is necessary to prevent permanent pain and disability. The instability of the reduced CMC joint requires frequent clinical and radiographic evaluation to evaluate for any postreduction subluxation.^{5,12}

Provide symptomatic care. Instruct the patient to elevate their hand and apply ice or cold packs several times a day. Nonsteroidal anti-inflammatory drugs (NSAIDs) supplemented with narcotic analgesics will alleviate the pain. Avoid giving the patient a splint to prevent locking of the elbow and shoulder. Instruct the patient to return to the Emergency Department immediately if they develop finger or hand numbness, increased pain, or tingling, which can signify the splint is too tight or a compartment syndrome.

COMPLICATIONS

There are usually no complications from the reduction. Neurologic or vascular damage can result from entrapment. This will be identified on a postreduction examination. **Consult a Hand Surgeon for immediate decompression in the Operating Room.** Capsular damage and edema may contribute to joint instability after closed reduction. Debris within the joint may prevent anatomic reduction. Chronic CMC dislocations or incomplete reductions can cause arthritis, chronic instability, decreased strength, pain, and stiffness.²³ Hand compartment syndromes can occur from the dislocations if the swelling is severe or from delaying the reduction.

SUMMARY

Carpometacarpal dislocations are a rare occurrence, usually stemming from high-velocity trauma. This injury can be easily missed and lead to long-term chronic pain and a loss of hand function. Early detection, evaluation by a Hand Surgeon, and appropriate management can minimize the risk of complications.

Metacarpophalangeal Joint Dislocation Reduction

Michael Gottlieb

INTRODUCTION

Hand injuries are among the most common injuries encountered in the Emergency Department (ED). They are responsible for 5% to 10% of ED visits, with approximately 6% of these patients having significant injuries.^{1,2} Many hand injuries occur from sports-related events or in the workplace. Data suggest that hand injuries account for 19% of lost-time injuries and 9% of workers' compensation cases.³ Approximately 3 to 4 million working days are lost each year as a result of hand injuries.⁴ It is estimated that 10% of patients with hand injuries require referral to a hand specialist.⁵ Proper motion and function of the hand are intimately related to normal anatomic alignment. The Emergency Physician (EP) must be skilled in the diagnosis and management of injuries about the hand. An improperly managed hand injury can result in significant disability that may include chronic pain, decrease range of motion, stiffness, joint swelling, deformity, or early degenerative arthritis.

Dislocations of the metacarpophalangeal (MCP) joint are relatively uncommon due to the relatively protected location of this joint in the hand.⁶ Injuries to the MCP joint of the thumb are more common than injuries to the other digits. Most of these injuries are to the collateral ligaments rather than a true dorsal or volar

FIGURE 106-1. Dislocations are classified by the position of the distal skeletal unit in relation to its proximal counterpart. **A.** Dorsal MCP joint dislocation. **B.** Volar MCP joint dislocation.

dislocation.⁷ The spectrum of injury to the ligaments extends from a minor stretch or sprain to a complete disruption.

The deformity caused by a joint dislocation is classified by the position of the distal skeletal unit in relation to its proximal counterpart. A dorsal MCP joint dislocation describes a dislocation in which the proximal phalanx is displaced in a dorsal direction relative to the metacarpal bone (**Figure 106-1A**). A volar MCP joint dislocation describes a dislocation in which the proximal phalanx is displaced in a volar direction relative to the metacarpal bone (**Figure 106-1B**).

ANATOMY AND PATHOPHYSIOLOGY

FUNCTIONAL ANATOMY

The metacarpals are tubular bones structurally divided into a head, neck, shaft, and base. When viewed in the sagittal plane, the metacarpal head has an increasing diameter beginning dorsally and extending along the articular surface to the volar side. When viewed in the coronal plane, the metacarpal head is pear-shaped or dumbbell-shaped, with the volar surface extending out of each side. The metacarpal head is broader in volar orientation which results in increasing bony stability as the joint is flexed. The volar plate, collateral ligaments, dorsal capsule, deep transverse intermetacarpal ligament, extensor tendon, and intrinsic tendons provide additional support and stability to the MCP joint.

The MCP joints are resistant to ligamentous injury and dislocation because of their inherent ligamentous structure, their surrounding supporting structures, and their protected position at the base of the fingers. The volar plate is a fibrocartilaginous structure that is attached firmly to the base of the proximal phalanx. It originates just proximal to the metacarpal head where it is thin and transparent. This allows for hyperextension of the MCP joint yet makes it vulnerable to injury during dorsal dislocations.

Side-to-side stability of the MCP joint is provided mainly by the collateral and accessory collateral ligaments and, to some extent, by the lumbrical and the interossei muscles and tendons.⁸ The collateral ligaments originate from the medial and lateral recesses in the metacarpal head and insert onto the base of the proximal phalanx. The eccentric configuration of the metacarpal head and the relatively fixed length of the collateral ligaments cause it to tighten when the joint is in flexion (**Figure 106-2**). This accounts for the limited abduction and adduction of the MCP joint in flexion as compared to the laxity in extension. The collateral ligaments of the MCP joint are most vulnerable to injury from forces directed ulnarly and dorsally. The accessory collateral ligament spans from the true collateral ligament to the volar plate, providing additional joint stability in extension. The central extensor tendon and sagittal band augment the thin dorsal capsule. The tendons of the palmar and dorsal interossei add a small degree of dynamic stability.

FIGURE 106-2. The shape of the metacarpal head is eccentric, making the collateral ligaments tighter in flexion (**A**) than in extension (**B**).

The interphalangeal (IP) joints are hinge joints, so motion only occurs as flexion and extension. The MCP joints are condyloid joints. The range of motion about the MCP joint includes 120° of flexion and 30° of hyperextension. It also has up to 30° of additional mediolateral laxity and a small degree of rotational laxity to facilitate an efficient grasp.⁹ **These differences are particularly important to consider when placing a splint that involves hand or finger immobilization. One must ensure proper positioning to minimize the risk of developing contractures. The preferred position of immobilization is with the IP joints in extension and the MCP joints in flexion.**

The opposable thumb is an essential structure for numerous activities. Despite its strong ligamentous and capsular support, the exposed positioning of the thumb makes it a frequent site of dislocations and subluxations. The MCP joint of the thumb is similar to those of the fingers but has a stronger volar plate and collateral ligaments with less side-to-side mobility.² The MCP joint of the thumb is also a condyloid joint with a quadrilateral rather than a spherical metacarpal head that allows mainly flexion and extension. However, it also permits some degree of abduction, adduction, and rotation. There is a large variability among individuals in the range of flexion and extension.

The metacarpal head is bicondylar, with the radial condyle being slightly larger. This structural difference provides the proximal phalanx of the thumb with a modest degree of pronation during flexion. Its range of motion consists of 15° to 20° of extension, 80° of flexion, and 10° of medial (i.e., adduction) and lateral (i.e., abduction) motion. Therefore, the range of motion of the MCP joint of the thumb is significantly more limited than that of the IP joints.

PATTERNS OF INJURY

First described by Kaplan in 1957, MCP joint dislocations are considerably less common than dislocations of the IP joints.¹⁰ Most MCP joint dislocations are dorsal, with volar MCP joint dislocations being a rare finding.^{11,12} Dislocation of any of the MCP joints in any direction is possible from hyperextension injuries. Dorsal dislocation of the thumb MCP joint is the most common type of all the MCP joint dislocations.

Hyperextension of the MCP joint results in the rupture of the volar plate. Injuries are classified as simple (i.e., reducible with a closed technique) or complex (i.e., irreducible with a closed technique). The collateral ligaments typically remain intact unless there is an associated twisting of the finger. Clinical and radiographic features can be used to differentiate simple from complex dislocations. In cases of simple dislocations, the joint usually hyperextends to approximately 90° and the volar plate is not interposed between the dislocated bones.¹³ The deformity is obvious with the finger in a claw position of extreme dorsiflexion at the MCP joint. In complex dislocations, the metacarpal and proximal phalanx usually lie more

parallel to each other with the metacarpal head causing a dimple on the volar skin. Complex MCP joint dislocations occur more frequently in the index finger. Clinical features that suggest a complex MCP dislocation include a proximal phalanx that is less acutely angulated than with a simple dislocation.² With complex MCP joint dislocations, the volar plate, sesamoids, flexor tendon, adductor tendons, extensor expansion, collateral ligaments, or joint capsule may become entrapped and prevent reduction.^{2,14-16} A widened joint space is seen on radiographs when the volar plate is interposed in the joint. This makes complex MCP dislocations difficult to manage.

The MCP joint of the thumb is very mobile. Dislocations of the thumb MCP joint are more common than the MCP joints of the fingers. The MCP joint can be dorsally dislocated by a hyperextension injury or shearing forces that ruptures the volar plate, joint capsule, and at least part of the collateral ligament. The proximal phalanx will come to rest in a position dorsal to the first metacarpal. Displacement of the proximal phalanx varies from a subluxation to the complete dislocation. For the latter to occur, the volar plate and the collateral ligaments must completely tear. Volar dislocations are rare and result from extensive tearing of the dorsal capsule and the extensor pollicis brevis tendon, leaving the joint very unstable.¹⁷

A simple MCP joint dislocation can be converted into a complex one during prolonged or repeated reduction attempts, especially those in which axial traction is the primary component.² This should not deter the EP from attempting a closed reduction for any MCP dislocation, but emphasizes the importance of using the appropriate technique.

RADIOGRAPHIC EVALUATION

Radiographic evaluation of all hand injuries is relatively straightforward. It should include at least three views (i.e., anteroposterior, oblique, and lateral) of the injured area. The most important radiographic error in evaluating joint injuries of the hand is failing to get a true lateral view of the injured joint. This may result in missing a fracture or a loose body in the joint.² Radiographic examination will show an obvious dislocation in the lateral view. Anteroposterior views may reveal widening of the joint space in complex dislocations. In addition, the sesamoid bones may be seen in the joint space, a pathognomonic sign for a complex MCP joint dislocation.

TOES

Metatarsophalangeal (MTP) joint dislocations of the toes are primarily dorsal. They occur secondary to an axial compression load to the digit, such as kicking a toe against a wall. MTP joint dislocations of the toe are reduced similarly to MCP dislocations of the finger.^{18,19} MTP joint dislocations can be difficult to reduce, as are MCP dislocations.²⁰

INDICATIONS

All MCP joint dislocations should have an initial attempt at reduction in the ED unless they are unstable, chronic, open, or associated with a fracture.²¹ This is true even if it is suspected to be a complex MCP joint dislocation.²² Reduction of the dislocation will provide significant pain relief. If a Hand Surgeon is not immediately available, an open MCP joint dislocation should be reduced after copious irrigation with sterile saline to remove any dirt and debris.

CONTRAINDICATIONS

Certain MCP joint dislocations require an immediate evaluation by a Hand Surgeon for open reduction and repair of any ligamentous or associated injuries. Closed reduction of an MCP joint dislocation

should not be performed in the ED for unstable, chronic, and open injuries. Instability in a joint through active range of motion indicates complete and multiple ligament disruption requiring an open surgical repair.^{2,23} Chronic injuries greater than 3 weeks old generally require surgical repair.²⁴

If the closed reduction attempt is unsuccessful in the ED, repeated attempts at reduction are contraindicated as a simple dislocation can be converted to a complex dislocation requiring an open surgical reduction. The ligaments, tendons, or sesamoid bones may become entrapped by bony and soft tissue structures in and around the MCP joint and prevent the reduction. Complex dislocations usually require open surgical reduction.^{22,25} Open MCP joint dislocations, whether reduced in the ED or not, will require operative management after initiation of antibiotics.

There are few contraindications to the use of local anesthesia solutions.²⁶ Relative contraindications include injection through infected skin, history of coagulopathy from heparin or warfarin therapy, factor deficiencies, liver dysfunction or bleeding disorder, or an allergy to the anesthetic medication. Another relative contraindication includes preexisting neurovascular damage prior to the procedure. Uncooperative patients can make the injection procedure technically more difficult and dangerous to perform. Refer to Chapter 153 for the details of the complications and contraindications of local anesthetics. Procedural sedation should be considered for these patients and children.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 18 gauge needle to draw up the local anesthetic solution
- 27 or 30 gauge needle, 2 inches long
- 10 mL syringe
- Alcohol swab
- Sterile gloves
- Sterile drapes
- Local anesthetic solution without epinephrine
- Equipment and supplies for procedural sedation (Chapter 159), if used
- Adhesive tape, ½ inch
- Webril padding
- Casting material
- Ace bandage
- Scissors

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare of the reduction to the patient and/or their representative. The patient must be aware that irreducible dislocations will require an open surgical reduction and possible repair of damaged structures within and surrounding the joint. Inform the patient that the injury can result in joint swelling for weeks to months and possibly permanent joint enlargement. Loss of motion with stiffness and residual soreness may last for months. Obtain an informed consent for the reduction procedure. An informed consent should also be obtained for the procedural sedation (Chapter 159), wrist block (Chapter 156), or the intraarticular injection (Chapter 97) if they are performed in addition to the reduction procedure.

Clean the involved joint of any dirt or debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Perform the wrist block (Chapter 156), the instillation of the local anesthetic

solution into the joint (Chapter 97), or procedural sedation and analgesia (Chapter 159) to facilitate the reduction attempt. **Make sure to perform a neurologic examination prior to anesthetizing the digit.**

TECHNIQUES

Early closed reduction may be easy provided that the thumb is maintained in adduction, the fingers are flexed, and the wrist is flexed to relax the intrinsic hand muscles.^{27,28} The major obstruction preventing reduction of the dislocated MCP joint is the displaced volar fibrocartilaginous plate lying between the proximal phalanx and the metacarpal head. Approximately 50% of MCP joint dislocations can be reduced in the ED using the closed technique.

DORSAL MCP JOINT DISLOCATIONS

Dorsal MCP joint dislocations (Figures 106-3 and 106-4A) require minimal, if any, distally applied traction for reduction. **It is important to remember that applying simple traction alone as an initial maneuver risks trapping the volar plate and transforming a simple dislocation into a complex dislocation.**

Hyperextend the MCP joint while simultaneously pushing the proximal end of the proximal phalanx volarly and over the metacarpal head (Figure 106-4B). This maneuver diminishes the potential buttonhole effect on the metacarpal neck that is caused by excess traction. Flex the MCP joint as the proximal phalanx returns to position (Figure 106-4C). Simultaneously flexing the IP joint and the wrist can help to relax the flexor tendons and make the reduction easier. This maneuver can sometimes relocate the displaced fibrocartilaginous plate to its normal position anterior to the metacarpal head.

FIGURE 106-3. Radiograph of a dorsal MCP dislocation of the index finger. (Used with permission from Kodama A, et al: Arthroscopic reduction of complex dorsal metacarpophalangeal dislocation of index finger. *Arthroscopy Tech* 2014; 3(2):e261–e264.)

FIGURE 106-4. Reduction of a dorsal MCP joint dislocation. **A.** Dorsal dislocation of the MCP joint. **B.** The deformity is exaggerated by hyperextension of the MCP joint as the proximal end of the proximal phalanx is pushed volarly and over the metacarpal head while simultaneously flexing the IP joint to relax the flexor tendons. **C.** The reduced MCP joint.

If the reduction is unsuccessful, repeated attempts to reduce the dislocation are contraindicated. Consider open reduction to disengage the metacarpal head from a probable buttonhole slit in the anterior capsule and from the surrounding muscles and tendons. Consult a Hand Surgeon for MCP joint dislocations that cannot be reduced after one attempt in the ED.

VOLAR MCP JOINT DISLOCATIONS

Volar MCP joint dislocations (Figures 106-5 and 106-6A) are generally associated with collateral ligament ruptures. They are commonly irreducible due to interposition of the extensor tendons and the dorsal joint capsule.²⁹ Consultation with a Hand Surgeon is often required for operative reduction.

FIGURE 106-5. Radiograph of a volar MCP dislocation of the thumb. (Used with permission from reference 29.)

FIGURE 106-6. Reduction of a volar MCP joint dislocation. **A.** Volar dislocation of the MCP joint. **B.** The deformity is flexed at the MCP joint as the proximal end of the proximal phalanx is pushed dorsally and over the metacarpal head. **C.** The reduced MCP joint.

Volar MCP joint dislocations require minimal, if any, distally applied traction for reduction. **It is important to remember that applying simple traction alone as an initial maneuver risks trapping the volar plate and transforming a simple dislocation into a complex dislocation.** Flex the MCP joint while simultaneously pushing the proximal end of the proximal phalanx dorsally and over the metacarpal head (Figure 106-6B). Extend the MCP joint as the proximal phalanx returns to position (Figure 106-6C).

If the reduction is unsuccessful, repeated attempts to reduce the dislocation are contraindicated. Consider open reduction to disengage the metacarpal head from a probable buttonhole slit in the anterior capsule and from the surrounding muscles and tendons. Consult a Hand Surgeon for MCP joint dislocations that cannot be reduced after one attempt in the ED.

MTP JOINT DISLOCATIONS OF THE TOES

MTP joint dislocations of the toes are primarily dorsal (Figure 106-7). They are reduced similarly to MCP dislocations of the finger.^{18,19} Like MCP dislocations, MTP joint dislocations can be difficult to reduce.²⁰

ALTERNATIVE TECHNIQUE

Some physicians use a finger trap (Instrument Specialists, Inc., Boerne, TX) with all the above mentioned reduction techniques. Insert the finger with the MCP dislocation and adjacent fingers in the finger trap (Figure 106-8). Adjust the height of the hanging finger trap so the elbow is flexed 90°. Attach a weight to the hanging arm, usually 5 or 10 pounds (Figure 106-8). This results in a distraction of the MCP joint and possibly a smoother and easier reduction.

ASSESSMENT

Assess the collateral ligaments for stability. **Because the goal of treatment is to restore functional stability, it is essential to perform a thorough evaluation of joint stability.** An accurate assessment generally requires adequate pain control, even in the most cooperative patients. Active stability is tested by allowing the patient to move the joint through the normal range of motion. Completion of a full range without displacement indicates adequate joint stability. Passive stability is assessed by applying gentle radial and ulnar stress to each collateral ligament and posteroanterior stress to assess volar plate integrity. Stress testing should be performed in both extension and flexion to avoid the stabilizing effect of the volar plate. Comparisons with the same joint of the uninvolved hand may

FIGURE 106-7. Radiograph of an MTP dislocation of the toe. (Used with permission from Bussouga M, et al: Irreducible dorsal metatarsophalangeal joint dislocation of the fifth toe: a case report. *J Foot Ankle Surg* 2010; 49:298.e17-298.e20.)

assist in the diagnosis.² A stable joint suggests that optimal functional recovery would result from short-term immobilization without requiring surgical intervention.

Joint stability of the thumb MCP joint is tested in full extension as well as in 30° of flexion. Complete ligament disruption is suspected if the joint can be stressed in a radial direction 25° to 35° beyond a similar stress to the patient's opposite thumb MCP joint. This instability should be demonstrated in both full extension and 30° of flexion. Flexion at 30° lessens the stabilizing effects of the volar plate.² The presence of ecchymosis suggests a complete ligament tear as well as a volar subluxation of the proximal phalanx.²⁶

Postreduction radiographs are important to demonstrate adequate reduction. Occasionally, a fracture is only visible on these views and not on the prereduction films.^{1,30} Joint subluxation after reduction is associated with interposed soft tissue or severe capsular injury.

AFTERCARE

Splinting of any MCP joint dislocation should focus on adequate immobilization and protection. Splinting is maintained for 1 week to 3 weeks. Prolonged splint use (e.g., greater than 3 weeks) can lead to joint stiffness. Simple dorsal finger MCP joint dislocation injuries should be splinted with the joints in 45° to 50° of flexion.² Volar finger MCP joint dislocations require splinting in complete extension. The thumb should be immobilized in a thumb spica splint in 20° of flexion for dorsal dislocations and in extension for volar dislocations for 3 weeks. A proper program of gradual active range-of-motion exercises should follow splinting.²⁵ With adequate protection and splinting of uncomplicated dislocations, athletes may return to activities within 1 to 2 weeks. Athletes involved in low-risk sports with minor injuries may return sooner while those requiring surgery will necessitate a longer recovery period.³⁰

COMPLICATIONS

Allergic reactions can occur from hypersensitivity to the local anesthetic solution. Symptoms can range from mild pruritus and urticarial rash to anaphylaxis. Severe allergic reactions to local anesthetics are extremely rare and the preservative in the anesthetic is often the culprit. The possibility of injury to structures in the joint may occur from improper insertion of the needle or needle movement within the joint cavity. Infection of the joint can also occur when the needle penetrates unclean skin, infected skin, or infected subcutaneous tissue. If proper aseptic technique is followed, the risk of infection is negligible. Refer to Chapters 97 and 153 regarding the complete details of joint injection complications and local anesthetic complications.

Complications of the reduction procedure are primarily related to failure of reduction, especially with complex dislocations. Entrapment of ligaments, tendons, or sesamoid bones can lead to an unsuccessful reduction.¹⁴ A simple MCP joint dislocation can be converted into a complex one during prolonged or repeated reduction attempts, especially those in which axial traction is a primary component of the reduction attempt.² Irreducible MCP joint dislocations require an immediate evaluation by a Hand Surgeon.³¹

Collateral ligament injuries occur infrequently and are often missed in the acute setting. The presence of an avulsion fracture from the metacarpal head or corner fracture of the base of the proximal phalanx suggests a collateral ligament injury. Consultation with a Hand Surgeon is recommended for patients with a collateral ligament injury. Some surgeons prefer immediate operative repair of these injuries. ED care involves immobilization in an ulnar gutter or clam digger splint with the MCP joint in 45° to 50° of flexion and appropriate referral.

Rupture of the ulnar collateral ligament of the thumb, also known as gamekeeper's or skier's thumb, results from a laterally directed force at the thumb MCP joint. This ligament is important to the grasping function of the thumb. **Early recognition of this injury is key.** The diagnosis is generally made through stress testing of the reduced MCP joint. Radiographs occasionally demonstrate an avulsion-type fracture. Treatment of partial ligament tears requires immobilization in a thumb spica splint for 6 weeks whereas complete rupture requires operative repair.

Radial collateral ligament injuries of the MCP joint of the thumb are less common but equally debilitating. The usual mechanism is forced adduction with or without hyperextension. The diagnosis is generally made through stress testing of the reduced MCP joint. Radiographs occasionally demonstrate an avulsion-type fracture. Treatment of partial ligament tears requires immobilization in a thumb spica splint for 6 weeks whereas complete rupture requires operative repair.

Degenerative arthritis may occur after multiple closed reductions or unrecognized chronic dislocation.³² Inadequate immobilization or early return to high-stress activities may result in ligamentous laxity or recurrent instability. Excessive joint contractures unresponsive to physical therapy may require surgical release.

SUMMARY

Injuries to the MCP joints of the hand are occasionally encountered in the ED. They may be associated with significant morbidity if not properly managed. The most common dorsal MCP joint dislocation seen is that of the thumb. Volar dislocations of the MCP joints are rarely seen. A thorough understanding of the anatomy and function of the MCP joint is essential to diagnose and manage these injuries. A detailed physical assessment of the soft tissues, bones, and neurovascular structures is essential to prevent occult injuries. Radiographic evaluation is required for all potential injuries. This should include anteroposterior, lateral, and oblique views in order to not miss associated avulsion fractures or evidence of complex dislocations. All MCP joint dislocations should have an attempt at reduction except those that are unstable, chronic, open, or associated with a fracture. A Hand Surgeon should evaluate any unstable, chronic, open, or irreducible dislocations. MCP joint dislocations reduced in the ED must be appropriately splinted and follow-up arranged with a Hand Surgeon.

Interphalangeal Joint Dislocation Reduction

Michael Gottlieb

INTRODUCTION

Dislocation of the interphalangeal (IP) joints is one of the most common orthopedic injuries seen in the Emergency Department (ED).¹⁻³ Most of these injuries occur during athletic activities. The proximal interphalangeal (PIP) joint is especially susceptible to injury during ball-handling sports.²⁻⁵ Among dislocations, IP joint injuries are second only to shoulder dislocations in incidence.⁴ While IP joint dislocations are generally easy to reduce, improperly treated injuries can result in chronic pain, swelling, restricted range

of motion, deformity, and early degenerative arthritis.^{1,6,7} Emergency Physicians must be proficient in diagnosing and treating IP joint dislocations.

ANATOMY AND PATHOPHYSIOLOGY

The bicondylar conformation of the PIP joint creates an inherently stable hinge joint limited to flexion and extension within a range from 0° to 120°. Additional stability comes from the complex of ligaments and tendons which form a box around the joint (**Figure 107-1**). The elements of this complex include the volar plate, lateral and collateral accessory ligaments, and the dorsal extensor tendons.¹⁰ The volar plate's dense, fibrous distal aspect attaches firmly to the middle phalanx while its more membranous proximal portion is continuous with the synovial reflection. This conformation resists dorsal dislocation at the joint.⁴ The three bands of the extensor tendon mechanism (i.e., the central slip with a lateral band on each side) provide dorsal support that resists joint dislocation (**Figures 107-2 and 107-3**). Lateral collateral ligaments bridge the PIP on the radial and ulnar sides, stabilizing it against lateral dislocation.³ Most dislocations are the result of hyperextension injuries. This results in the distal bone displacing dorsally. This damages the volar plate. The volar plate can be interposed in the joint space making the dislocation irreducible. This can sometimes be unlocked during the reduction with hyperextension.

The less commonly dislocated IP joints (i.e., finger distal interphalangeal [DIP] and thumb IP joints) are similar in anatomy to one another. They are more broad-based than the PIP and range from 0° in extension to 90° in flexion with no significant lateral or rotary movement.³ The distal phalanx in both joints is firmly attached to the skin, accounting for the high percentage of open dislocations involving these joints.

Dislocations of the PIP joint are the most common and may be classified as dorsal, volar, and lateral (**Figure 107-4**).^{1,4,11} Each type of dislocation results from a different mechanism of injury and has specific associated complications.

Dorsal or posterior dislocations are the most common type of PIP joint dislocation (**Figures 107-4A**).¹² They usually result from hyperextension injuries.^{4,8,9} A dorsal dislocation occurs when the middle phalanx is displaced dorsally from the proximal phalanx. These dislocations involve injury to the volar plate and may be associated with an avulsion fracture of the base of the middle phalanx (**Figures 107-4B and 107-5**). Avulsion fractures involving greater than 30% of the articular surface are considered unstable and require referral to an Orthopedic or Hand Surgeon.⁴

Volar or anterior PIP joint dislocations are far less common, but more severe than dorsal PIP joint dislocations (**Figures 107-4C and 107-6**).

FIGURE 107-1. A schematic drawing of the box complex surrounding the PIP joint.

FIGURE 107-2. Dorsal view of the extensor mechanism.

They occur from a simultaneous axial load and a rotational force on the IP joint. Volar PIP joint dislocations are associated with rupture of the collateral ligament and disruption of the central slip of the extensor tendon mechanism. These injuries may preclude closed reduction.⁴ These injuries can be more difficult to diagnose than other types of dislocations, often presenting as a subtle subluxation at the PIP joint with rotational deformity of the middle and distal phalanx seen on plain films.¹³

If left untreated, volar PIP joint dislocations may result in a boutonniere deformity (**Figure 107-7**).^{1,12,14,15} This injury should be suspected in patients with pain over the PIP joint and the inability to fully extend the digit against active resistance. Plain films are usually unremarkable. Splinting in full extension and early follow-up with an Orthopedic or Hand Surgeon are mandatory in all suspected cases.

Lateral PIP joint dislocations are uncommon (**Figure 107-4D**).³ They result from a pure radial or ulnar force on the joint with either partial or complete rupture of the collateral ligament. Ulnar dislocation with radial collateral ligament injury is six times more common than radial dislocation with ulnar collateral ligament disruption.³ Lateral PIP joint dislocations are often able to be reduced by closed methods.

Distal IP joint dislocations and IP joint dislocations of the thumb (**Figure 107-8**) are rare. They are most commonly caused by a direct blow to the distal portion of the digit.⁸ They are most often dorsally

FIGURE 107-3. Lateral view demonstrating the anatomy of supporting structures. The volar plate and collateral ligaments form a box around three sides of the joint, while the extensor mechanism (consisting of central and lateral slips) lies along the dorsal aspect of the joint.

FIGURE 107-4. Dislocations of the PIP joint. They are classified based on the relationship of the distal bone to the proximal bone. **A.** Dorsal or posterior dislocation. **B.** Dorsal dislocation with an associated fracture. **C.** Volar, ventral, or anterior dislocation. **D.** Lateral dislocation.

FIGURE 107-5. Lateral view of a dorsal dislocation with minor avulsion fracture involving less than 30% of articular surface. This is a stable fracture-dislocation.

FIGURE 107-6. Volar dislocation with an associated fracture of the middle phalanx.

FIGURE 107-7. The boutonniere deformity.

dislocated and frequently open due to the firm attachment of the distal phalanx to the subcutaneous tissue and skin. All open dislocations require immediate Orthopedic or Hand Surgeon consultation.

IP joint dislocations of the toes are primarily dorsal. They occur secondary to an axial compression load to the digit, such as kicking a toe against a wall. IP joint dislocations of the toe are reduced similarly to dorsal IP dislocations of the finger.¹⁶

INDICATIONS

Most IP joint dislocations that present to the ED are amenable to closed reduction by the Emergency Physician. Factors to be considered include time from injury, closed versus open dislocation, associated fracture patterns, and direction of the dislocation. The majority of IP joint dislocations present within hours of the injury, and closed reduction may be safely performed up to 3 weeks from the time of injury.⁷ If there is no disruption of the skin overlying an IP joint dislocation, it is considered a closed injury and suitable for closed reduction. Small fractures involving less than 30% of the joint surface are also considered safe for closed reduction.³

The direction of the dislocation should be considered prior to any attempted reduction. Most dorsal dislocations are reducible by

FIGURE 107-8. Dorsal dislocation of the thumb IP joint.

closed methods. Open reduction is occasionally necessary due to interposition of the ruptured volar plate or trapping of the proximal phalanx between the volar plate and flexor tendon.¹⁷ Lateral dislocations are also successfully managed by closed reduction in most cases.¹⁷

The management of volar dislocations is more controversial. These injuries are often irreducible with closed methods due to trapping of soft tissue in the joint space (e.g., usually the ruptured extensor mechanism) or are unstable after reduction due to extensive damage to the supporting ligaments.¹⁷ **A single attempt at closed reduction may be performed.** If successful, splint the finger in extension and consult an Orthopedic or Hand Surgeon as open repair of the extensor mechanism is usually required to prevent a boutonniere deformity.^{13,17} **All irreducible injuries require emergent consultation with an Orthopedic or Hand Surgeon.**

CONTRAINDICATIONS

Contraindications to closed reduction of IP joint dislocations include chronic dislocations, open dislocations, unstable dislocations, or complex dislocations. A chronic dislocation is defined as an IP joint dislocation of longer than 3 weeks in duration. These injuries generally require open reduction and should not be reduced in the ED.⁸ The digit should be carefully inspected for any breaks in skin integrity. Any skin wound, especially in the direction of the dislocation, mandates treatment as an open dislocation by an Orthopedic or Hand Surgeon. Unstable injuries are generally fracture-dislocations involving greater than 30% of the articular surface.³ Complex injuries involve complete disruption of multiple ligaments or tendons surrounding the joint and often require open reduction and repair due to interposition of disrupted soft tissues between the articular surfaces of the IP joint.^{1,8,18,19}

EQUIPMENT

DIGITAL BLOCK

- Povidone iodine or chlorhexidine solution
- 27 gauge needle, 2 inches long
- 5 mL syringe
- Alcohol swab
- Local anesthetic solution without epinephrine (1% lidocaine, 0.25% or 0.5% bupivacaine)

POSTREDUCTION SPLINT

- Aluminum finger splint with foam padding
- Gauze padding
- Adhesive tape, ½ inch
- Scissors

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Obtain a written consent for the reduction procedure. **Inform the patient that up to 30% of PIP and DIP joint injuries may remain swollen for many months and will likely result in permanent joint enlargement. Loss of motion and residual soreness may last several months.**^{1,7}

The use of local anesthesia is based on physician and patient preference. Many physicians and patients believe that the pain of reduction is less than that of a digital block and more tolerable. For this reason, many physicians will reduce an IP joint dislocation without the use of local anesthesia.

Clean the finger of any dirt and debris. Apply povidone iodine solution and allow it to dry. Insert a 27 gauge needle into the lateral aspect of the base of the proximal phalanx. Inject 0.5 mL of local anesthetic solution. Redirect the needle dorsally while depositing 1 mL of local anesthetic solution. Withdraw the needle and redirect it volarly while depositing 1 mL of local anesthetic solution. Repeat the procedure on the medial aspect of the base of the proximal phalanx. Refer to Chapter 156 for a more detailed description of the methods to anesthetize a finger.

TECHNIQUES

DORSAL DISLOCATION OF THE PIP JOINT

A dorsal dislocation of the PIP joint involves a partial or complete disruption of the volar plate. Most dorsal dislocations of the PIP joint are easily reduced (**Figure 107-9**). Firmly grasp the middle phalanx of the affected finger with the dominant hand. Grasp the base of the proximal phalanx with the nondominant hand. Hyperextend the PIP joint and apply longitudinal traction to separate the articular surfaces (**Figure 107-9B**). The nondominant hand is used to stabilize the proximal phalanx and apply countertraction. Flex the PIP joint while maintaining traction and apply dorsal pressure on the base of the middle phalanx (**Figure 107-9C**). This should restore the proper alignment of the proximal and middle phalanx.

Immobilize the reduced PIP joint in 30° of flexion for approximately 3 weeks (**Figure 107-9D**). Alternatively, tape the injured finger to an adjacent unaffected finger (i.e., “buddy taping”). Gauze padding must be placed between the fingers before “buddy taping” to prevent skin breakdown. During immobilization, it is important to avoid hyperextension if the finger is buddy taped as this may lead to further injury of the volar plate. The presence of an avulsion fracture involving less than 30% of the articular surface does not alter this management plan.

Rarely, a dorsal dislocation can be irreducible due to interposed soft tissue or impingement of the proximal phalangeal head between the central slip and the lateral bands.¹³ This type of dislocation is referred to as “complex.” **Failure of two or more attempts at closed reduction should raise the suspicion of an irreducible joint and an Orthopedic or Hand Surgeon should be consulted.**

FIGURE 107-9. Reduction technique for an IP joint dislocation. **A.** Dorsal PIP joint dislocation. **B.** Exaggerate the deformity by hyperextending the middle phalanx and applying longitudinal traction distal to the injury. **C.** Flex the PIP joint while applying pressure to the dorsum of the middle phalanx with continued traction. **D.** The PIP joint is placed in 30° of flexion for splinting.

VOLAR DISLOCATION OF THE PIP JOINT

Volar dislocations of the PIP joint are almost always accompanied by an injury to the central slip of the extensor tendon causing an inability to extend the PIP joint (**Figure 107-7**). These dislocations are generally irreducible and need early consultation with an Orthopedic or Hand Surgeon for operative repair due to the extensive soft tissue damage.²⁰ Although controversial, some authors recommend a single attempt at closed reduction by applying a longitudinal (distal) force, hyperextending the joint, and applying dorsal pressure to the base of the middle phalanx. During this procedure, the metacarpophalangeal and DIP joints should be flexed and the wrist extended to relax the anteriorly displaced lateral bands and extensor mechanism. Splint the joint in extension and arrange for early follow-up with an Orthopedic or Hand Surgeon if closed reduction is achieved. **It is important to splint in complete extension, as even mild flexion or “buddy taping” may lead to a boutonniere deformity (Figure 107-7).**

LATERAL DISLOCATION OF THE PIP JOINT

Lateral dislocations of the PIP joint involve a partial or complete rupture of the radial and ulnar collateral ligaments. There is a 6:1 ratio of radial to ulnar collateral ligament tears with the digit being displaced in the opposite direction of the ligament rupture.³ Generally, reduction is easy and the joint is stable after the procedure. Recreate the injury and apply longitudinal (i.e., distal) traction to the finger. Bring the distal phalanx in line with the proximal phalanx.

After reduction, determine by physical examination if the collateral ligaments are partially or completely torn. “Buddy tape” the finger to the adjacent finger for 3 weeks for incomplete collateral ligament tears. Early active motion of the finger is encouraged after this time. Complete collateral ligament tears are repaired operatively and require early consultation by an Orthopedic or Hand Surgeon.

DISLOCATION OF THE IP JOINT OF THE THUMB

Dislocations of the IP joint of the thumb are rare.²¹ The injury is usually dorsal and open. If the dislocation is closed, the joint can be reduced in the same manner as PIP dislocations of the fingers.¹⁸ Splint the reduced joint in slight flexion and arrange for early follow-up by an Orthopedic or Hand Surgeon. It may be irreducible due to the volar plate, flexor pollicis longus tendon, sesamoid bone, or a fracture fragment.²²

DISLOCATION OF THE DIP JOINT

DIP joint dislocations are rare, usually dorsal, and open.²³ They are easily reduced in a similar manner to other IP joint dislocations and are generally stable after reduction.^{19,24} Reduction is accomplished by application of longitudinal (distal) traction, hyperextension of the distal phalanx, and the application of dorsal pressure on the base of the distal phalanx. Immobilize only the DIP joint with a dorsal splint in 5° to 10° of flexion. Arrange for follow-up with an Orthopedic or Hand Surgeon.

The DIP joint may be irreducible if there is an avulsion and entrapment of the volar plate in the joint, entrapment of the long flexor tendon in the joint, or entrapment of a bony fragment.²⁵ Immediate consultation with an Orthopedic or Hand Surgeon should be sought if the DIP joint is irreducible.

ALTERNATIVE TECHNIQUE

Some physicians use a finger trap (Instrument Specialists, Inc., Boerne, TX) with all the above mentioned reduction techniques. Insert the distal phalanx of the finger with the PIP or DIP

FIGURE 107-10. The hand and arm suspended in a finger trap. (Photo courtesy of Instrument Specialists, Inc., Boerne, TX.)

dislocation and the distal phalanges of the adjacent fingers in the finger trap (**Figure 107-10**). Adjust the height of the hanging finger trap so the elbow is flexed 90°. Attach a weight to the hanging arm, usually 5 or 10 pounds (**Figure 107-10**). This results in a distraction of the PIP and DIP joint and possibly a smoother and easier reduction.

ASSESSMENT

Fully evaluate the finger after the reduction or any reduction attempt. This requires the local anesthetic injection to wear off. This may be the reason to use lidocaine over bupivacaine. **Perform and document a complete neurologic and vascular exam of the finger. An Orthopedic or Hand Surgeon should be consulted immediately if any neurologic or vascular deficits are identified.** Obtain postreduction radiographs of the digit to identify an avulsion injury or an incomplete reduction. Test the joint for functional stability by having the patient actively move the injured finger through a full range of motion. Stability of the joint is maintained if the collateral ligaments and volar plate are intact and no subluxation or dislocation occurs. Test the collateral ligaments by applying radially and ulnarly directed stresses with the joint in 20° of flexion. Test the integrity of the volar plate by having the patient hyperextend the joint and comparing the range of motion to that of the other fingers. The joint is considered stable if there is no displacement during active range of motion and passive stressing of the joint. If stable, place the joint in an appropriate splint and refer the patient to an Orthopedic or Hand Surgeon for follow-up. Immediately consult an Orthopedic or Hand Surgeon if the joint is not easily reduced or if it is not stable after the reduction. All open dislocations require immediate evaluation by an Orthopedic or Hand Surgeon for irrigation, reduction, and closure.

AFTERCARE

Splinting of any finger injury should provide adequate immobilization and protection while allowing maximal range of motion of the unaffected joints. The method of splinting for each specific dislocation is described in the Technique section.

COMPLICATIONS

Most complications of IP joint dislocations are secondary to the injury itself rather than the reduction procedure.²⁶⁻²⁸ Even seemingly minor injuries can have complications such as prolonged swelling, pain, and stiffness. A thorough evaluation of the digit, prompt diagnosis, and proper treatment will help minimize these complications.

Complications of the reduction procedure are primarily related to failure of reduction. Entrapment of soft tissues should be suspected in cases with multiple failed attempts at reduction.²⁰ Numerous attempts at reduction may lead to trauma at the articular surface, predisposing to the development of premature degenerative arthritis. Irreducible or complex IP joint dislocations require an immediate evaluation by an Orthopedic or Hand Surgeon.

Prolonged or improper splinting of a joint can lead to chronic complications. Extended splinting and immobilization can lead to permanent joint stiffness. In general, IP joints should not be immobilized for greater than 3 weeks. **Inappropriate splinting of a volar dislocation in even mild flexion may lead to long-term complications such as the boutonniere deformity.**^{14,15}

“Buddy taping” is problematic. There is a low patient compliance rate and it can cause skin adhesion or damage from the tape or rubbing of the fingers.²⁹ Gauze padding must be placed between the fingers before “buddy taping” to prevent skin breakdown. During immobilization, it is important to avoid hyperextension if the finger is buddy taped as this may lead to further injury of the volar plate. The “buddy taping” can also become loose.

SUMMARY

Injuries to the IP joints of the hand are commonly encountered in the ED and may be associated with significant morbidity. The most common injury encountered is a dorsal IP joint dislocation. Other dislocations include volar and lateral IP joint dislocations. A thorough understanding of the anatomy and function of the IP joint is essential to diagnose and treat these common injuries appropriately. A detailed physical examination of the soft tissues, bones, and neurovascular structures is necessary. Radiographic evaluation is required for all potential injuries, including an anteroposterior and a lateral view of the affected digit. Acute stable dislocations can be reduced immediately in the ED. An Orthopedic or Hand Surgeon should evaluate any unstable, chronic, open, or complex dislocation. Joints reduced in the ED must be splinted and appropriate follow-up arranged.

Hip Joint Dislocation Reduction

Michael Gottlieb

INTRODUCTION

Hip dislocations are true orthopedic emergencies that the Emergency Physician must be capable of reducing. Neurovascular damage to the hip and leg is a known consequence of hip dislocations. Avascular necrosis (AVN) may occur in up to 20% of patients with a hip dislocation, with some studies showing that AVN following a hip dislocation occurs in a time-dependent fashion. In other

words, the longer a hip is dislocated, the higher the incidence of AVN.¹ Dislocation for more than 6 hours almost universally results in AVN.²⁻⁴ A hip dislocation can be diagnosed clinically with the help of radiologic studies.⁵ The advantages of plain films and computed tomography (CT) scans, over the use of ultrasonography, are to identify associated fractures.

The most common causes of hip dislocations are traumatic dislocations of a normal hip, mechanical dislocations of a prosthetic hip, spontaneous dislocations, and pathologic dislocations. Dislocations may occur with minor mechanisms at the extremes of age. Examples include falling from a standing height for elderly patients or during athletic activities in children.^{6,7}

Many techniques have been described to reduce dislocated hips.^{3,8-15} The Emergency Physician must be familiar with each of these techniques and how to apply them appropriately to optimize patient management and outcome. Dislocations of both normal and prosthetic hips are seen in the Emergency Department, with prosthetic hip dislocations now occurring more commonly than normal hip dislocations.¹⁶⁻¹⁸ Although these are not associated with AVN, the pressure from the dislocated prosthetic head may still result in other neurovascular complications.

ANATOMY AND PATHOPHYSIOLOGY

Ball-and-socket joints are inherently stable. The strong muscles, ligaments, and fibrous joint capsule of the hip further reinforce this innate stability. Consequently, in the average adult, a great deal of force must be transmitted to dislocate the hip. This is significant, as the patient with a hip dislocation may have other life-threatening injuries that take precedence over the management of the hip dislocation. The increased mortality rate associated with a hip dislocation typically results from associated injuries of the head, thorax, or pelvis.

Hip dislocations are classified into anterior, posterior, inferior, and central based on the relationship of the dislocated femoral head to the acetabulum.^{2,7} Anterior hip dislocations account for 5% to 10% of hip dislocations and occur with the leg in a neutral or abducted position. The femoral head is pushed anterior to the coronal plane of the acetabulum. These patients present in extreme pain with the hip and knee flexed to 90° and the leg held in external rotation. A slight shortening of the leg may also be noted, but this is difficult to detect with the knee in flexion. There are three subtypes of an anterior hip dislocation: anterior obturator, anterior iliac, and anterior pubic. In anterior obturator dislocations, the femoral head displaces medially and lies in the obturator canal. In anterior iliac dislocations, the femoral head moves superiorly and lies over the iliac wing. In anterior pubic dislocations, the femoral head moves inferiorly over the pubic ramus.

Posterior hip dislocations are the most common type, accounting for nearly 90% of all hip dislocations. This is because the posterolateral half of the femoral neck lies outside the joint capsule and results in weaker posterior support of the hip. Posterior dislocations result from force transmitted along the femoral shaft with the leg adducted. The most common mechanism of injury is a motor vehicle collision where the knees strike the dashboard and the femoral head is pushed posterior to the coronal plane of the acetabulum. The leg will be shortened and internally rotated with marked knee flexion and adduction of the thigh. The femoral head is rarely visible but may be palpable in the buttock region. Posterior hip dislocations are further categorized into posterior ischial and posterior iliac subtypes. In posterior ischial dislocations, the femoral head is displaced inferiorly and lies over the ischium. In posterior iliac dislocations, the femoral head is displaced superiorly and lies over the iliac wing.

Central hip dislocations are the rarest form. In central dislocations, the femoral head remains on the same coronal plane as the acetabulum but is displaced superiorly. Most central hip dislocations are associated with acetabular fractures.

Inferior hip dislocations are the rarest form of hip dislocations. They are difficult to reduce due to buttonholing of the femoral head through the inferior joint capsule. An inferior dislocation usually involves forceful abduction and external rotation. A special type of inferior dislocation is luxatio erecta of the hip.¹⁹ Reduction is usually easy due to the destruction of most of the hip ligaments during the dislocation. This makes the hip unstable and most reductions do not stay reduced.

INDICATIONS

All hip dislocations must be reduced. **Emergent hip reduction by the Emergency Physician is indicated when distal neurologic or vascular deficits are present or if the Orthopedic Surgeon is not immediately available.** The incidence of AVN is time-dependent and necessitates reduction as soon as possible to limit this complication.

CONTRAINDICATIONS

Any life-threatening conditions must be treated before the hip is reduced. Closed reduction is contraindicated if a surgical indication for repair exists. Surgical exploration is required for hip dislocations associated with femoral head fractures, femoral shaft fractures, or the finding of sciatic nerve dysfunction. Surgery is also indicated for an irreducible dislocation, persistent instability of the joint after closed reduction, and any postreduction neurovascular deficits.

EQUIPMENT

- Procedural sedation equipment and supplies (Chapter 159)
- Assistants
- Sheets

PATIENT PREPARATION

The patient must be appropriately stabilized. Life-threatening associated injuries and comorbid conditions must be adequately addressed. Obtain plain radiographs to define the anatomic

dislocation pattern, rule out any associated fractures, and guide relocation attempts. Explain the risks, benefits, complications, and aftercare of the reduction procedure and obtain an informed consent from the patient and/or their representative. **The patient must be sedated to achieve optimal muscle relaxation and pain control.** Perform procedural sedation (Chapter 159) after obtaining a separate informed consent for this procedure.²⁰

TECHNIQUES

Hip reduction techniques have been described with the patient in every imaginable position.^{9-16,21} The relative success rates for each technique have not been reliably reported.¹⁶ Therefore, physicians typically use the technique(s) with which they are most comfortable. The reader should become familiar with multiple reduction techniques in case one or more are unsuccessful.

ALLIS MANEUVER

This is one of the most common hip reduction methods (**Figure 108-1A**). It was first described by Allis in 1893.⁹ The technique has been improved by the addition of procedural sedation. Place the patient supine and perform procedural sedation. Instruct an assistant to stabilize the patient's pelvis to the gurney by pressing down on the anterior superior iliac spines. It may be necessary for the assistant to use both hands on the side of the pelvis associated with the hip dislocation to stabilize the pelvis. The patient's hips may also be stabilized by tying a sheet around the patient's anterior superior iliac spines and the bed. Flex the affected knee and hip to 90°. Grasp the affected knee with both hands behind the knee (**Figure 108-1A-(1)**). Apply axial traction to the thigh with incrementally increasing force. Simultaneously rotate the femur laterally and medially until the hip relocates (**Figure 108-1A-(2)**).

If relocation is not easily accomplished, instruct a second assistant to apply lateral traction to the inner thigh of the affected proximal femur (**Figure 108-1B**). Repeat the entire procedure with the addition of lateral traction to reduce the dislocation.

MODIFIED ALLIS MANEUVER

This technique incorporates all of the maneuvers described above. Additionally, place the hip in maximum adduction. Apply longitudinal traction to the femur while an assistant presses down on the pelvis with one hand and pushes the head of the affected femur toward the acetabulum with the other hand.

FIGURE 108-1. The Allis maneuver. **A.** An assistant stabilizes the pelvis. The physician simultaneously distracts the femur (1) and rocks it medial to lateral (2, curved arrow). **B.** The same maneuver with the addition of a second assistant to apply lateral traction to the thigh.

FIGURE 108-2. The gravity method of Stimson. **A.** An assistant stabilizes the pelvis. The physician applies downward pressure on the calf (1, straight arrow) while applying subtle and external rotation to the femur (2, curved arrow). **B.** An alternative method.

GRAVITY METHOD OF STIMSON

Place the patient prone on the gurney. Perform procedural sedation. Monitoring may be more difficult due to the prone positioning. **Extra attention must be paid to the patient's airway and breathing when placed prone.** Associated injuries may preclude prone positioning of the patient.

Place the affected leg hanging over the side of the gurney with the knee and hip each flexed 90°. Alternatively, hang both legs off the distal edge of the gurney with the knees and hips flexed 90° (**Figure 108-2A**). Instruct an assistant to hold the patient down on the gurney by applying downward pressure on the posterior pelvis at the posterior superior iliac spines.

Grasp the ankle in one hand to support the limb and to be able to apply internal and external rotation to the extremity (**Figure 108-2A-(1)**). Place the other hand on the proximal posterior calf. Exert gradual longitudinal traction on the femur by placing pressure on the affected calf until the hip relocates. A subtle internal and external rotary motion (**Figure 108-2A-(2)**) may help to assist the femoral head over the acetabular rim. **Care must be taken not to compress the structures in the popliteal fossa with excessive pressure behind the knee.**

A much greater degree of force can be applied to the hip if the physician places a knee in the affected popliteal fossa instead of pushing with their arm (**Figure 108-2B-(1)**). Pull the affected ankle upward while simultaneously exerting downward force on the calf to reduce the dislocation. A subtle internal and external rotary motion (**Figure 108-2B-(2)**) may help to assist the femoral head over the acetabular rim.

WHISTLER/ROCHESTER/TULSA TECHNIQUE

This technique was described at three separate sites (**Figure 108-3**). Whistler Health Care Center in Vancouver, Canada, described it in 1997.²² The Orthopedic Associates of Rochester described it in 1999. Vosburgh described it in 1995 as the Tulsa method.²³ It is reported to be easier than other techniques and can be performed without the aid of an assistant.^{22,23} Pelvic stabilization is provided by a counterforce on the uninjured knee. The force and counterforce occur through the same fulcrum and are therefore exactly equivalent.²¹

Place the patient supine. Perform procedural sedation. Stand to the side of the affected hip. Flex the unaffected knee 130°. Place your elbow under the affected knee, allowing the leg to dangle over your forearm (**Figure 108-3**). Reach to grasp the flexed unaffected knee with the palm. Grasp the affected ankle with your other hand in order to flex the knee and rotate the hip. The hold is now established (**Figure 108-3**).

Elevate the affected knee by raising your shoulder and using your arm as a lever (**Figure 108-3-(1)**). Simultaneously apply a longitudinal force by progressively flexing the patient's knee over your arm (**Figure 108-3-(2)**). This applies traction to the femoral head, moving it anteriorly and around the acetabular rim. Once the acetabular rim is cleared, externally rotate the leg to allow the femoral head to reduce (**Figure 108-3-(3)**). External rotation is achieved by swinging the ankle laterally. A pop should be felt as the femoral head falls into the acetabulum. Reduction can be verified by internal

FIGURE 108-3. The Whistler (or Rochester, or Tulsa) technique. Elevation of the physician's shoulder (1) while simultaneously flexing the patient's knee (2) moves the femoral head anteriorly and around the acetabular rim. Externally rotating the patient's leg (3, curved arrow) by swinging the ankle laterally allows the femoral head to reduce.

and external rotation of the hip. An assistant may occasionally be required to stabilize the pelvis.

MODIFIED FULCRUM TECHNIQUE

Lefkowitz described the fulcrum technique in 1993 and it was modified by Bergman as described in 1994.¹⁴ The modified technique has been used successfully in the Emergency Department.⁸ The advantage of this technique is that leverage allows greater reduction forces to be applied to the hip with less strength and effort on the part of the physician (Figure 108-4). A steady and constant force can easily be applied that reduces the risk of fractures and nerve injuries. This constant traction is superior to the sudden jerks that are inevitable in some of the other reduction techniques.¹⁴

Place the patient supine and perform procedural sedation. Secure the patient to the gurney with a sheet or use an assistant to stabilize the patient's pelvis. Lower the bed, preferably to within 2 to 3 feet of the floor. Stand on the side of the affected hip. Place one foot on the edge of the bed at the level of the patient's hip. A platform or footstool may be used to gain a mechanical advantage if the level of the bed is too high or you are too short.

Flex the affected knee 90° over your knee (Figure 108-4). Grasp and hold the ankle of the affected leg. Apply steady and gentle downward traction on the ankle to flex the knee while simultaneously plantarflexing your foot on the gurney. This will cause the knee to exert an upward force on the patient's knee, raising the femoral head around the edge of the acetabulum and reducing the hip. **Do not use the patient's knee as the fulcrum.**^{8,24,25} **Pushing down on the patient's lower leg with the physician's knee fixed creates much force on the patient's knee and can cause damage to the knee ligaments.** It may be necessary to gently rotate the affected foot internally and externally if the hip does not reduce easily.

FIGURE 108-4. The fulcrum technique. The physician applies downward pressure on the patient's ankle while simultaneously plantarflexing their foot to move the femoral head around the acetabular rim and reduce the hip.

SIMPLE LONGITUDINAL TRACTION

This technique is similar to the reduction of a shoulder dislocation (Figure 108-5). Place the patient supine and perform procedural sedation. Extend the affected lower extremity at the hip and knee.

FIGURE 108-5. The simple longitudinal traction technique. An assistant applies lateral traction to the thigh while the physician simultaneously applies in-line traction to the leg.

Wrap a sheet around the affected proximal thigh. Grasp the patient's ankle with both hands. **Do not grasp the foot as this can result in secondary injury.** Instruct an assistant to apply lateral traction to the sheet and proximal thigh to move the femoral head over the acetabular rim while simultaneously exerting longitudinal traction to the leg by pulling on the patient's ankle to reduce the hip (**Figure 108-5**).

The editor prefers to use a padded leather restraint around the affected ankle. Wrap the two ties of the restraint around your hips and secure them with a knot. You can then slowly lean backward to allow your body weight to reduce the hip. This method is especially useful if you are small in stature or do not have significant upper

body strength. Do not wrap the ties around your waist as this can cause low back strain.

BIGELOW MANEUVER

Bigelow described this technique in the literature in 1870 (**Figure 108-6**). It was the first documented hip reduction technique. Perform procedural sedation. Place the patient supine with the affected hip and knee flexed 90°. Hold the affected knee in the crook of your flexed elbow with the patient's foot in the opposite hand (**Figure 108-6A**). Instruct an assistant to stabilize the pelvis

FIGURE 108-6. The Bigelow maneuver. **A.** The physician applies upward traction on the femur while an assistant stabilizes the pelvis. **B.** The hip is externally rotated and extended while the femur is distracted.

by applying downward pressure to the anterior superior iliac spines. Lift your shoulder and arm supporting the patient's knee to apply distal traction to the femur (**Figure 108-6A**). Externally rotate and extend the hip while distracting the femur to reduce the hip (**Figure 108-6B**).

Although this is considered the “classic” reduction technique, it is disadvantageous in that it requires great strength on the part of the physician to reduce the hip. The force applied is often jerking and inconsistent. The aid of a strong assistant is required to stabilize the pelvis.

LATERAL REDUCTION TECHNIQUE

This technique was described in 1986 by Skoff.^{16,26} It gives a mechanical advantage to the physician as most of the force exerted is by the physician's own body weight (**Figure 108-7**). It also capitalizes on the principle of recreating the position of injury in order to exactly reverse the forces of the injury to produce the reduction.

Place the patient in the lateral decubitus position lying on the unaffected extremity. Perform procedural sedation. Flex the affected hip 100° and allow it to gravitate to adduction. This position recreates the typical position of the hip during the dislocation. Internally rotate the patient's hip 45° while maintaining 45° of adduction to exaggerate the hip dislocation. Place a looped sheet around the patient's hips and an assistant's hips. Place a second looped sheet around the patient's knee and your own hips. The use of sheets allows optimal leverage by using body weight as the reduction force. Grasp the affected ankle to maintain the patient's knee flexed at 90°. Apply distal traction to the femur by slowly leaning backward while the assistant simultaneously applies posteriorly directed countertraction to the femoral head. The assistant can use their hands to apply a distally directed force to the femoral head to assist in the reduction.

ASSESSMENT

The appropriate evaluation of any dislocation requires a thorough pre- and postreduction neurologic and vascular examination of the distal extremity. Any neurologic or vascular deficits require immediate evaluation by an Orthopedic Surgeon. Obtain a postreduction radiograph to confirm the reduction and rule out any fractures missed on the initial radiographs or as a result of the reduction procedure. Monitor the patient until they recover from the procedural sedation. A CT scan may help identify any acetabular or osteochondral fractures.

AFTERCARE

All patients with a hip dislocation require an evaluation by an Orthopedic Surgeon. All native hip dislocations and most prosthetic hip dislocations require hospitalization and traction after reduction.²⁷

COMPLICATIONS

The complications of a hip dislocation itself are fractures, AVN of the femoral head, injury to the sciatic and femoral nerve, and injury to the femoral artery.²⁷ Posttraumatic arthritis, recurrent dislocation, and myositis ossificans can also occur.²⁸ Complications may occur despite the most expedient treatment and prosthetic hip replacement may become necessary.

The complication of AVN is time-dependent. Reductions delayed over 6 hours are at significant risk for AVN. The risk of AVN increases as the time of the dislocation increases. Reductions that apply steady, nonjerking force to the limb have a lower incidence of associated fractures as well as fewer neurovascular complications. Multiple attempts at reduction are also associated with an increased

FIGURE 108-7. The lateral reduction technique. The hip is flexed 100°, adducted 45°, and rotated internally 45°. The physician applies traction to the femur. The assistant applies countertraction while simultaneously applying distally directed pressure on the femoral head with their hands.

risk of AVN. More than three attempts at closed reduction are associated with an increased risk of AVN and should prompt the Emergency Physician to seek orthopedic consultation.²⁹

Neurologic injury is one of the most common complications of hip dislocations, even when successful closed reduction is achieved. Sciatic nerve neurapraxia, from peroneal nerve branch damage, occurs in up to 15% of adult traumatic dislocations, although symptoms resolve in 60% to 70% of cases.³⁰ Sciatic nerve dysfunction may lead to an equinus deformity and will need immediate consultation with an Orthopedic Surgeon.³⁰ Nerve entrapment and dysfunction can occur following closed reduction techniques.³¹

SUMMARY

Multiple techniques exist to reduce hip dislocations. The Emergency Physician should master several techniques in order to provide the best care to these patients, limit complications, and enhance outcomes. The sooner a dislocated hip is reduced, the fewer the potential complications.

Patellar Dislocation Reduction

Mark P. Kling

INTRODUCTION

Dislocation of the patella generally results from a traumatic event.^{1,2} It is most commonly due to a direct blow to the flexed knee. It may also occur from a forceful quadriceps contraction while the femur is internally rotated on the tibia with the foot planted (e.g., baseball, football, and soccer). Many patients may not notice the dislocation as it may spontaneously reduce immediately after the injury. There are numerous theories as to the predisposition to a patella dislocation (e.g., adolescents, age 10 to 30, anteverted femur, contracted iliotibial groove, excessive patellar lateral tilt, family history of patella dislocation, females, flat intercondylar groove, joint laxity, “knock-knees” or genu valgus, hypoplastic femoral condyle, large Q-angles, ligamentous laxity, obesity, patella alta, patellar hypermobility, physical activity, shallow intercondylar groove, and vastus medialis muscle atrophy).³⁻⁶ This condition is most commonly seen in adolescents and females.^{7,8}

ANATOMY AND PATHOPHYSIOLOGY

The knee consists of the patellofemoral and the tibiofemoral joints. The patellofemoral joint is a gliding joint. The patella is an oval-shaped sesamoid bone that develops in the tendon of the quadriceps muscle. It is suspended between the quadriceps superiorly and the tibial tuberosity inferiorly. The patella articulates between the femoral condyles. It is held in place by the vastus medialis muscle, the medial retinaculum, the medial and lateral patellofemoral ligaments, and the patellotibial ligament.

The patella may dislocate in numerous directions (**Figure 109-1**). Lateral dislocations are the most common type (**Figure 109-2**).⁸ The patella usually dislocates laterally due to its asymmetrical shape and the normal upward and lateral pull of the quadriceps muscle. The patella may dislocate intraarticularly, medially, and superiorly in rare instances (**Figure 109-1**).⁸⁻¹³

The clinical determination of a lateral patellar dislocation is usually simple and obvious (**Figure 109-3A**).⁸ The knee is held in partial flexion. The patella can be seen and palpated on the lateral surface of the knee. This may be accompanied by edema and/or ecchymoses over the anterolateral knee.⁸

FIGURE 109-1. Types of patellar dislocations.

Pain over the parapatellar ligaments may be the only clinical sign in patients whose patellar dislocation has spontaneously reduced. The physical examination usually reveals mild edema in the parapatellar recesses. There is often laxity in the tendons and ligaments surrounding the patella. A patellar apprehension test is generally positive. The knee joint is usually stable.

The pathophysiology of this dislocation may include abnormalities secondary to hyperelasticity, laxity, and malalignment of the joint. Osteochondral fractures are common and seen on

arthroscopy.^{3,4,14} Arthroscopy, bone scans, and magnetic resonance imaging scans are considerations for further evaluation and diagnosis of the patellofemoral joint by the Orthopedic Surgeon.

Obtain prereduction radiographs (**Figure 109-3B**) to document patellar fractures or other bony abnormalities prior to the reduction. Obtain radiographs in multiple views (e.g., anteroposterior, axial, lateral, notch, and sunrise). These may be difficult to obtain if the patient has significant discomfort and may be delayed until after the reduction. Radiographs may be used to identify a foreign body if abrasions or lacerations are present over the knee. **The patella often reduces spontaneously in the radiology suite as the leg is extended to obtain the radiographs.**

INDICATIONS

Reduce any medial or lateral patellar dislocation that does not reduce spontaneously. The goal is prompt reduction to decrease articular surface injury.⁸

CONTRAINDICATIONS

The evaluation and management of the patient's airway, breathing, circulation, and other significant injuries take priority over the reduction of a patellar dislocation. There are a few relative contraindications to the reduction of a patellar dislocation. Consult an Orthopedic Surgeon for the evaluation and reduction if the dislocation is horizontal, intercondylar, superior, or associated with fractures of the distal femur or proximal tibia. **The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity.** This requires immediate reduction by the Emergency Physician if, after phone consultation, the Orthopedic Surgeon is not immediately available to perform the reduction.

EQUIPMENT

No special equipment is required for the reduction of a patellar dislocation. A knee immobilizer or splinting material (i.e., plaster, fiberglass, or prepackaged splints) should be available to temporarily splint the patella after the reduction.

FIGURE 109-2. Anatomy of a lateral patellar dislocation. **A.** Anteroposterior view. **B.** Lateral view.

A

B

FIGURE 109-3. The lateral patellar dislocation. **A.** The presentation is often clinically dramatic. **B.** Radiograph. (Photos used with permission from www.lifeinthefastlane.com.)

PATIENT PREPARATION

Patient preparation is minimal in the case of a lateral or medial patellar dislocation. Explain the risks, benefits, complications, and aftercare to the patient and/or their representative. Obtain an informed consent prior to performing the procedure. Verbal consent is usually sufficient since the reduction of a patellar dislocation is relatively simple with infrequent complications. Place the patient supine on a gurney. No intravenous access, premedication, or sedation is required for this procedure. The Emergency Physician may administer analgesics after the initial examination to make the patient more comfortable during radiography and while waiting for

FIGURE 109-4. Reduction of a lateral patellar dislocation. **A.** Manipulation of the knee begins with gradual extension. **B.** Medially directed pressure applied to the patella when the knee is fully extended reduces the dislocation.

the reduction. Consider the use of a femoral nerve block if anesthesia is required (Chapter 156).¹⁵

TECHNIQUES

The technique for the reduction of a lateral patellar dislocation is simple (**Figure 109-4**). Slightly flex the patient's hip to release the tension on the quadriceps muscles. Slowly and gently extend the knee (**Figure 109-4A**). The patella may relocate spontaneously by simply extending the knee. Apply gentle and medially directed pressure to the lateral surface of the patella if it is still dislocated (**Figure 109-4B**). This will allow the patella to move into its normal anatomic position in the intercondylar fossa of the femur. The technique to reduce a medially dislocated patella is similar except for the application of a laterally directed force on the patella.

Intraarticular and horizontal patellar dislocations are sometimes reduced by closed manipulation, although most require open reduction. Case reports have described irreducible lateral dislocations.¹⁶ Superior patellar dislocations require operative reduction. **Do not reduce intercondylar and superior dislocations in the Emergency Department unless hemodynamic compromise is present.** Patients with these types of patellar dislocations require urgent consultation with an Orthopedic Surgeon and possible hospital admission for reduction in the Operating Room.

PEDIATRIC CONSIDERATIONS

Most pediatric injuries occur during athletics.⁸ This is in contrast to adults that are often sedentary and overweight. The indications, contraindications, and technique are the same as for adults. Some studies show children do better in the long term with surgical management.¹⁷ Other studies show no difference between nonsurgical and surgical management.¹⁸

ASSESSMENT

Obtain a postreduction radiograph to rule out any osteochondral fractures that were not diagnosed initially and to ensure positioning of the patella. Maintain the knee in extension by immobilization with a splint or knee immobilizer until follow-up for reevaluation (Chapter 113).

AFTERCARE

The Orthopedic Surgeon may elect to take a conservative approach with the leg in a long leg cast and the knee in full extension for 6 weeks.^{6,19} Some Orthopedic Surgeons believe that all first-time dislocations should be repaired surgically. A phone consultation with an Orthopedic Surgeon is recommended before the patient is discharged home.

The general principles of orthopedic care can be applied.⁸ These include rest, ice, elevation, and nonsteroidal anti-inflammatory drugs (NSAIDs). Narcotic analgesics are not necessary or required in most cases. The patient should follow up with an Orthopedic Surgeon in 5 to 7 days. Surgical versus conservative treatment will be evaluated at that time to determine the best outcome.²⁰ The patient will most likely need physical therapy. The instability and resultant tracking abnormalities will require isometric, proprioceptive, and strength rehabilitation.^{6,21} Patients placed in splints or casts should use crutches and not bear weight on the affected extremity. Consider crutches for those placed in a knee immobilizer.

COMPLICATIONS

The damage to ligaments from the dislocation can result in a hemarthrosis. Twisting can damage the anterior cruciate ligament, lateral collateral ligament, medial collateral ligament, and/or meniscus. Patellar dislocations are subject to degenerative arthritis, osteochondral fractures that may be difficult to diagnosis initially, and recurrent dislocations or subluxations.⁸ No complications are associated with the reduction procedure.

SUMMARY

Patellar dislocations are common. The reduction of a lateral or medial patellar dislocation is a safe, simple, and gratifying procedure. Education of the patient and follow-up with an Orthopedic Surgeon are requirements for successful rehabilitation.

110

Knee Joint Dislocation Reduction

Michael Gottlieb

INTRODUCTION

Dislocations of the knee are rare. They are true orthopedic emergencies and have a significant association with soft tissue injuries and neurovascular compromise. A dislocated knee occurs most commonly after a major force is applied to the knee joint such as from a motor vehicle collision, other high-speed trauma, or a sports injury. The etiology has recently been changing to also occur during activities of daily living and other low-level trauma, especially in obese patients.¹⁻⁴ A dislocated knee can occur after a total joint replacement.⁵ The forces necessary to cause a dislocation of the knee joint can often fracture the bones of the leg.

Complete dislocation of the knee joint results in a gross deformity that is confirmed by plain radiographs. Reduction by the Emergency Physician may be reasonable if the Orthopedic Surgeon is not immediately available or if the injured extremity shows signs of distal neurologic or vascular compromise.

A careful examination of the distal extremity must be performed and documented.⁶ **It must include an assessment of the capillary refill, the dorsalis pedis pulse, the posterior tibial pulse, peroneal nerve function, and tibial nerve function.**

ANATOMY AND PATHOPHYSIOLOGY

A knee dislocation is the displacement of the tibiofemoral articulation (**Figure 110-1**). It can involve the rupture of the anterior cruciate ligament, the posterior cruciate ligament, the joint capsule, or the collateral ligaments of the knee.⁷ Anterior knee dislocations are the most common type of knee dislocation. This injury is defined as anterior displacement of the tibia relative to the femur (**Figures 110-1A and 110-2**). It results from an acute hyperextension injury to the knee joint that ruptures the anterior cruciate ligament as well as part of the posterior cruciate ligament and the posterior joint capsule. The collateral ligaments usually remain intact. Tibial spine fractures, osteochondral fractures of the tibia or femur, and meniscal injuries can be associated with the rupture of the anterior cruciate ligament. In children, hyperextension injuries are more likely to cause a distal femoral epiphyseal separation rather than a complete dislocation.

FIGURE 110-1. The classification of knee dislocations. **A.** Anterior. **B.** Posterior. **C.** Lateral. **D.** Medial. **E.** Rotary.

An anterior knee dislocation may be associated with a popliteal artery injury in 30% to 40% of patients.⁸ The popliteal artery is at particular risk for injury because it is anchored proximally at the adductor hiatus and distally at the soleus arch. The collateral circulation around the knee joint is relatively poor. Therefore, disruption of the popliteal artery may result in significant distal ischemia and limb loss if the reduction is delayed. **It is important to note that the presence of distal peripheral pulses and capillary refill does not preclude an arterial injury.**⁹

The peroneal nerve is tethered as it winds around the fibular neck. As a result, peroneal nerve injury is another common complication occurring in up to 23% of patients with knee dislocations. Nearly one-half of patients with peroneal nerve injuries have a permanent deficit.¹⁰ Therefore, it is particularly important to examine the peroneal nerve for dysfunction (i.e., anesthesia or paresthesia on the lateral aspect of the leg and impaired dorsiflexion of the foot).

A posterior knee dislocation is defined as the posterior displacement of the tibia relative to the femur (**Figure 110-1B**). It occurs less commonly than an anterior knee dislocation. It results from a direct force applied to the anterior tibia with the knee slightly flexed which ruptures the posterior joint capsule and both cruciate ligaments. The collateral ligaments usually remain intact. It is associated with popliteal artery damage and disruption of the extensor mechanism of the knee joint.

Medial, lateral, and rotary dislocations of the knee joint are less common than anterior or posterior knee dislocations

(**Figures 110-1C, 110-1D, and 110-1E**). Medial knee dislocations result from an adduction force on the tibia that ruptures the lateral collateral ligament, the posterior joint capsule, and both cruciate ligaments. Damage to the peroneal nerve is common while injury to the popliteal artery is not. Lateral knee dislocations result from an abduction force on the tibia that ruptures the medial collateral ligament, the posteromedial joint capsule, and both cruciate ligaments. Neurovascular injuries are uncommon with a lateral knee dislocation.

Rotary dislocations are subdivided into posterolateral and posteromedial types. Posterolateral rotary dislocations result from an anteromedial force on the tibia that ruptures the posterior and medial joint capsule, partially avulses the gastrocnemius, damages the menisci, and has an associated chondral fracture. Posteromedial rotary dislocations result from an anterolateral force on the tibia that ruptures both cruciate ligaments, the medial collateral ligament, and the posteromedial joint capsule; partially avulses the gastrocnemius; damages the menisci; and has an associated chondral fracture. Both of these rotary dislocations are associated with peroneal nerve and popliteal artery injuries.

Medial, lateral, and rotary dislocations of the knee are uncommon injuries that should be managed by an Orthopedic Surgeon.^{11,12} The reduction technique for these dislocations is quite similar to that for the reduction of anterior or posterior knee dislocations. The rotary knee dislocation is often irreducible in the Emergency Department.

FIGURE 110-2. Radiograph of an anterior knee dislocation. (Used with permission from reference 16.)

Although the presentation of a knee dislocation is usually clinically obvious, patients can present after a spontaneous reduction.¹³ **This type of injury is classified as an occult dislocation and can be easily missed if one does not maintain a high index of suspicion.** A hemarthrosis suggest a knee fracture, knee dislocation, or intraarticular ligamentous rupture.¹⁴

Anteroposterior and lateral radiographs of the knee will confirm the diagnosis of a knee dislocation (**Figure 110-2**).² Postreduction films should include at least two planes to detect occult fractures of the tibial spine, the distal femoral physis, or the proximal tibial physis. Consider a postreduction stress view if damage to the collateral ligaments is suspected. Radiographs of the pelvis and hip should also be considered to rule out any associated injuries.

INDICATIONS

Any dislocation of the knee joint requires prompt reduction, ideally within 6 to 8 hours after the injury. The incidence of limb loss is greater than 85% if the knee is dislocated longer than 6 to 8 hours.¹⁵

Knee dislocations associated with distal neurologic or vascular insufficiency require immediate reduction. This includes children with open growth plates.¹⁶

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a dislocated knee joint. Reduction of the knee joint may be performed intraoperatively if the patient requires surgery for other reasons. An Orthopedic Surgeon should reduce the knee if it is dislocated medially, laterally, or rotatorily; if it is associated with fractures of the extremity; or if the joint is open. **Emergent reduction by the Emergency Physician is indicated if the Orthopedic Surgeon is not immediately available or if there is evidence of distal neurologic or vascular compromise.**

EQUIPMENT

- Procedural sedation equipment and supplies (Chapter 159)
- Assistants
- Compressive cotton wrap (Webril)
- Splinting material
- Elastic bandage

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The necessary postprocedural care should also be discussed. Obtain an informed consent for the reduction procedure as well as for the procedural sedation. Place the patient supine on a gurney. Prepare for and apply procedural sedation (Chapter 159). **The key to performing this procedure is to have the patient adequately sedated and their muscles relaxed.**

TECHNIQUES

ANTERIOR KNEE DISLOCATION REDUCTION

Reduction of an anterior knee dislocation is usually performed without difficulty using a modified traction-countertraction technique (**Figure 110-3**). Instruct an assistant to grasp the tibia and apply in-line traction while a second assistant grasps the thigh and applies countertraction. **It is extremely important to avoid putting pressure over the popliteal fossa as this can injure the structures traversing that space.** The physician then pushes the proximal tibia posteriorly (**Figure 110-3-(1)**) while the distal femur is simultaneously lifted anteriorly into anatomic position (**Figure 110-3-(2)**).

FIGURE 110-3. Reduction of an anterior knee dislocation. An assistant applies in-line traction to the tibia while a second assistant applies countertraction to the femur. The proximal tibia is pushed posteriorly (1) while the distal femur is pulled anteriorly (2) to reduce the dislocation.

FIGURE 110-4. Reduction of a posterior knee dislocation. An assistant applies in-line traction to the tibia while a second assistant applies countertraction to the femur. The proximal tibia is pulled anteriorly to reduce the dislocation.

Do not allow the knee to become hyperextended during the reduction as this may further injure the neurovascular structures located within the popliteal fossa.

Some physicians feel that the reduction procedure may be easier to perform if the patient is in the prone position. Performing the procedure in the prone position can be a more challenging position to attain if other injuries are present and makes monitoring during procedural sedation difficult. Therefore, placing the patient in the prone position is not recommended.

POSTERIOR KNEE DISLOCATION REDUCTION

Reduction of a posterior knee dislocation is similar to that of an anterior knee dislocation. The two assistants provide in-line traction and countertraction while the physician grasps the proximal tibia and pulls it anteriorly into anatomic position (**Figure 110-4**).

MEDIAL KNEE DISLOCATION REDUCTION

Reduction of a medial knee dislocation is similar to that of the anterior knee dislocation. The two assistants provide in-line traction and countertraction while the physician grasps the proximal tibia and pulls it laterally into anatomic position.

LATERAL KNEE DISLOCATION REDUCTION

Reduction of a lateral knee dislocation is similar to that of the anterior knee dislocation. The two assistants provide in-line traction and countertraction while the physician grasps the proximal tibia and pulls it medially into anatomic position.

ROTARY KNEE DISLOCATION REDUCTION

Reduction of a posteromedial knee dislocation is similar to that of the anterior knee dislocation. The two assistants provide in-line traction and countertraction while the physician grasps the proximal tibia and simultaneously externally rotates and lifts it upward into anatomic position.

Reduction of a posterolateral knee dislocation should be performed in the Operating Room unless neurologic and/or vascular compromise to the distal leg is present. These dislocations are often irreducible using closed reduction techniques because the medial femoral condyle evaginates through the medial joint capsule in a process known as “buttonholing.”¹¹ This dislocation requires open reduction under general anesthesia.

PROSTHETIC KNEE DISLOCATION

The reduction of prosthetic knees is similar to native knees. The preprocedural and postprocedural care is also the same.

ASSESSMENT

Immediately evaluate and document the neurologic and vascular status of the distal extremity after any attempts at reduction. Any decrease in sensation, motor function, or pulses require immediate angiography or computed tomography (CT) angiography and operative intervention. Immediate operative intervention can avoid limb ischemia and amputation.¹⁷ Obtain postreduction radiographs to confirm proper anatomic alignment, to identify any fractures not evident on the prereduction radiographs, and to rule out the displacement of any fracture fragments.¹⁸ Stress radiographs are recommended if injury to the collateral ligaments is suspected.

AFTERCARE

The postprocedural care of the knee joint is as important as the initial reduction. Immobilize the extremity in a posterior long leg splint with the knee in 15° of flexion. Administer analgesics as necessary to control the patient's pain.

All patients require admission to the hospital for observation and monitoring of the distal neurovascular status of the extremity and the development of a compartment syndrome.² Arteriography or CT angiography can be obtained to exclude injury to the popliteal artery, especially if there is any irregularity in the dorsalis pedis pulse, posterior tibial pulse, or ankle-brachial index before or after the reduction (**Figure 110-5**). Arteriography or CT angiography may not be necessary if the distal pulses are normal before and after the reduction and if the ankle-brachial index is normal. However, the vascular status should be closely monitored for 48 to 72 hours after the reduction.¹⁹⁻²¹

The mandatory use of arteriography or CT angiography to evaluate vascular injuries in all patients after reduction may not be necessary.^{19,22-24} In select patients who have a normal physical examination and a normal ankle-brachial index angiography may be avoided. However, this is a decision that should be made in consultation with the Orthopedic Surgeon who will be managing the patient.

An inpatient magnetic resonance imaging (i.e., magnetic resonance imaging with magnetic resonance angiography) scan of the knee joint should be obtained to evaluate ligamentous injury.² The patient may require reconstructive surgery, especially if they are young and physically active.²⁵

COMPLICATIONS

Knee dislocations are true orthopedic emergencies because of the potential for associated vascular and neurologic injuries. Complications are primarily related to injuries of the neurovascular structures within the popliteal fossa. These include the popliteal artery and peroneal nerve. Patients are also at risk of knee instability, knee arthrosis, knee stiffness, and chronic pain.^{26,27} Neurovascular

FIGURE 110-5. Angiogram of a popliteal artery disruption. Note the abrupt cutoff. **A.** Anteroposterior view. **B.** Lateral view with the collaterals backfilling the popliteal artery. (Used with permission from reference 22.)

injuries increase as body mass index increases.¹ These can lead to the development of a compartment syndrome.²

Anterior knee dislocations have a high incidence of associated vascular injuries usually involving the popliteal artery. Of these, up to one-half can result in amputation of the leg.²⁸ Nerve damage has been reported in the literature to occur in 20% to 40% of knee dislocations.²⁹ **It is important to specifically assess for injuries to these structures. Avoid direct pressure to the popliteal fossa during the reduction and hyperextension of the knee after the reduction to prevent iatrogenic neurovascular damage.** Injuries to neurologic and vascular structures can also occur during the reduction attempt. These include lacerations, traction injuries, and entrapment between the tibial plateau and the femoral condyles.

Irreducible dislocations may be secondary to interposed soft tissue, ligamentous instability, buttonhole tears in the medial joint capsule, or entrapment of the medial femoral condyle.^{1,2,30} These patients require operative reduction under general anesthesia by an Orthopedic Surgeon.

SUMMARY

Knee dislocations occur after significant trauma to the knee joint. Fortunately, knee dislocations are rare events. They are associated with significant morbidity and require prompt reduction to restore the normal alignment of the bony structures. Arteriography to rule out damage to the popliteal artery and a magnetic resonance imaging scan to rule out soft tissue injuries should be performed after the knee joint has been reduced and adequately splinted. All patients require admission for observation and may require reconstructive surgery. Frequent neurovascular evaluation is extremely important during the hospitalization. Evidence of distal leg ischemia requires immediate surgical exploration.

Ankle Joint Dislocation Reduction

Crystal Ives Tallman

INTRODUCTION

The foot and the ankle are commonly injured parts of the body. Fractures of the ankle associated with dislocations of the ankle joint (i.e., fracture-dislocations) or isolated ankle dislocations without fracture are serious injuries that can lead to long-term morbidity. Ankle dislocations are high-energy injuries that occur most commonly in young people from sports, falls, or motor vehicle collisions.¹⁻³ The ankle mortise and surrounding ligaments make the ankle joint strong and stable. This makes isolated ankle dislocations uncommon. Ankle dislocations are usually associated with malleolar fractures or a fracture of the tip of the tibia. They are open 25% of the time. There are limited data on the mechanism of injury. Most ankle dislocations lead to posterior or posteromedial displacement and occur from a force against a plantarflexed foot. Definitive management of fracture-dislocations is most often surgical. The patient benefits from early analgesia and prompt reduction.

Ankle dislocations can be successfully reduced in the Emergency Department with the use of procedural sedation and longitudinal traction-countertraction. The key to a successful outcome is anatomic restoration and healing of the ankle mortise.¹ Postreduction management involves leg immobilization and consultation with an Orthopedic Surgeon. Some closed ankle dislocations may be

managed nonoperatively with good long-term results from a closed reduction and casting for 6 to 9 weeks.⁴⁻⁸

ANATOMY AND PATHOPHYSIOLOGY

The ankle joint is composed of the talus, tibia, and fibula. The inferior articular surface of the tibia is concave in both the coronal and sagittal planes. The articular surface of the talus is broader anteriorly and longer on its medial and lateral aspects.⁹ The ankle mortise limits rotation of the talus and make the ankle joint inherently stable.

There are three groups of ligaments that provide added stability to the ankle joint. It is stabilized laterally by the anterior talofibular, the calcaneofibular, and the posterior talofibular ligaments (**Figure 111-1**). It is stabilized medially by the deltoid ligament. The deltoid ligament comprises a group of four adjoining ligaments: the anterior and posterior tibiotalar, the tibionavicular, and the tibio-calcaneal ligaments (**Figure 111-2**). The third group of ligaments stabilizes the tibia to the fibula and forms the tibiofibular syndesmosis. This includes the anterior and posterior tibiofibular ligaments.

Almost all ankle dislocations are associated with partial or complete ligamentous ruptures (**Figure 111-3**).¹⁰ They are often associated with malleolar and distal fibula fractures due to the relative strength of the ligaments compared to the malleoli.^{1,2,11} This results in one or both malleoli fracturing rather than the ligaments tearing with a lateral fracture-dislocation.

Posterior or posteromedial ankle dislocations are the most commonly described dislocations of the ankle joint due to the tendency to land with the ankle pronated and inverted after a fall from a height (**Figures 111-3A and 111-4**).^{2,6,12} Lateral ankle fracture-dislocations are commonly seen (**Figure 111-3B**). Posterior ankle dislocations are associated with posterior marginal fractures of the tibia. An anterior ankle dislocation is rare and usually associated with a fracture of the anterior margin of the tibia (**Figure 111-3C**). The talus may also dislocate laterally or medially if the tibiofibular ligaments are disrupted or a fracture of one or both malleoli occurs. Due to the low incidence of reported ankle dislocations without fractures, data on the mechanism of injury are incomplete.¹³ A posteromedial ankle dislocation occurs when a force is applied against the posterior distal tibia with the foot plantarflexed. Anterior ankle dislocations occur from a forcible dorsiflexion of the foot (e.g., fall on the heel with the foot dorsiflexed) or from a force applied to the distal anterior tibia while the foot is fixed. Injury to the tibiofibular joint is variable and the fibula may be dislocated posteriorly or anteriorly. Diastasis of the tibiofibular syndesmosis is uncommon. Lateral ankle dislocations are always associated with fractures of the malleoli. They occur from a force on the distal fibula with the foot fixed to the ground. Superior ankle dislocations are uncommon (**Figure 111-3D**).¹⁴⁻¹⁶ They occur when a force from above is driven through the leg and to the ankle (e.g., a fall from a height).

Physical examination often reveals the type of ankle dislocation. Prominence of the talus and a change in the length of the foot are common. Neurovascular injury is uncommon with closed ankle dislocations. There is a higher incidence of neurovascular injury with open dislocations. Ankle dislocations are associated with a risk of vascular injury and the development of a compartment syndrome from severe swelling.¹² Most vascular injuries are to the dorsalis pedis or posterior tibial vessels and may be accompanied by damage to the adjacent superficial peroneal nerve or sural nerve, respectively.^{1,9} Tibiotalar dislocations rarely result in avascular necrosis.

INDICATIONS

All closed ankle fracture-dislocations and isolated dislocations should be reduced urgently to protect the soft tissues, decrease swelling, and minimize articular injury. Some authors

FIGURE 111-1. The bony and ligamentous structures of the lateral ankle.

recommend reduction prior to radiography.¹⁷ **Any dislocation, open or closed, that has evidence of distal neurologic or vascular compromise must be reduced emergently.** Extreme lateral deviation may compromise the dorsalis pedis artery and requires prompt reduction.¹⁷ All open dislocations require intravenous antibiotics,

irrigation, surgical debridement, and reduction by an Orthopedic Surgeon in the Operating Room. However, reduction should occur in the Emergency Department if the Orthopedic Surgeon or the Operating Room is not immediately available.⁵ Some physicians will reduce dislocations that are intact neurovascularly but the skin

FIGURE 111-2. The bony and ligamentous structures of the medial ankle.

FIGURE 111-3. Types of ankle dislocations. **A.** Posterior. **B.** Lateral. **C.** Anterior. **D.** Superior.

is tense from the dislocation. This prevents skin necrosis over the ankle joint.

CONTRAINDICATIONS

There are no absolute contraindications to reducing a dislocated ankle. Some authors would not recommend Emergency Department reduction of an open fracture-dislocation without evidence of neurovascular compromise or in a setting where immediate orthopedic and operative intervention was available.

EQUIPMENT

- Local anesthetic solution
- 18 gauge needle
- 22 gauge needle, 2 inches long

FIGURE 111-4. Radiograph of a posterior ankle dislocation.

- Equipment and supplies for procedural sedation (Chapter 159)
- Equipment and supplies for intravenous (IV) regional anesthesia (Chapter 157)
- Stockinette
- Compressive wrap (e.g., Webril)
- Plaster, fiberglass, or commercially prepared splinting material
- Elastic bandage

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the reduction procedure and the procedural sedation to the patient and/or their representative. Obtain an informed consent for both procedures. Place the patient supine with the affected foot at the edge of the gurney. Patients should be premedicated with an opioid analgesic prior to the procedure and ideally prior to radiography. Procedural sedation (Chapter 159) provides excellent analgesia, muscle relaxation, and sedation. It allows the reduction procedure to be more tolerable for both the patient and the Emergency Physician. Intraarticular lidocaine (Chapter 97) has been reported as an effective alternative to conscious sedation for closed reduction of ankle fracture dislocations.¹⁸ Alternatives include IV regional anesthesia (i.e., Bier block) of the lower leg (Chapter 157) and ultrasound-guided distal popliteal sciatic nerve block (Chapter 156).¹⁹

TECHNIQUES

The techniques described below to reduce ankle dislocations have three things in common. The hip and knee are flexed to relieve the tension on the gastrocnemius and soleus muscles. The foot is flexed (i.e., plantarflexed or dorsiflexed) to unlock or disengage the talus. Finally, the talus is maneuvered into its proper anatomic position.

LATERAL ANKLE DISLOCATIONS

Flex the patient's hip and knee by placing a pillow behind their knee. Grasp the calcaneus with one hand and the forefoot with the other hand (**Figure 111-5A**). Instruct an assistant to grasp the patient's calf. Apply distal traction to the heel while the assistant provides countertraction to the leg (**Figure 111-5A**). The next step is to rotate the foot medially so that the great toe is in alignment with the anterior tibia while simultaneously dorsiflexing the foot and distracting the heel (**Figure 111-5B**). The talus will reduce easily with a palpable and audible "clunk."

FIGURE 111-5. Closed reduction of a lateral ankle dislocation. **A.** The heel is distracted while an assistant provides countertraction. **B.** Simultaneously, medially rotate and dorsiflex the foot while distracting the heel.

POSTERIOR ANKLE DISLOCATIONS

Flex the patient's hip and knee by placing a pillow behind their knee. Grasp the calcaneus with one hand and the forefoot with the other hand (**Figure 111-6A**). Instruct an assistant to grasp the patient's calf. Simultaneously apply distal traction to the heel and plantarflex the foot while the assistant provides countertraction to the leg (**Figure 111-6A**). The next step is to dorsiflex the foot while distracting the heel and a second assistant provides posteriorly directed pressure on the distal leg (**Figure 111-6B**). The talus will reduce with a palpable and audible "clunk."

ANTERIOR ANKLE DISLOCATIONS

Flex the patient's hip and knee by placing a pillow behind their knee. Grasp the calcaneus with one hand and the forefoot with the other hand (**Figure 111-7A**). Instruct an assistant to grasp the patient's calf. Simultaneously apply distal traction to the heel and dorsiflex the foot until the toes point upright while the assistant provides countertraction to the leg (**Figure 111-7A**). The next step is to push the foot posteriorly while distracting the heel and a second assistant provides anteriorly directed pressure on the distal leg (**Figure 111-7B**). The talus will reduce with a palpable and audible "clunk."

SUPERIOR ANKLE DISLOCATIONS

Superior ankle dislocations are associated with significant soft tissue and articular damage. Neurovascular injury is uncommon with

FIGURE 111-6. Closed reduction of a posterior ankle dislocation. **A.** The heel is distracted and the foot is plantarflexed while an assistant provides countertraction. **B.** The foot is dorsiflexed while the heel is distracted and a second assistant applies posterior traction on the distal leg.

FIGURE 111-7. Closed reduction of an anterior ankle dislocation. **A.** The heel is distracted and the foot is dorsiflexed until the toes are upright while an assistant provides countertraction. **B.** The foot is pushed posteriorly while the heel is distracted and a second assistant applies anterior traction on the distal leg.

these dislocations. Superior ankle dislocations should be reduced, splinted, and managed by an Orthopedic Surgeon. The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.

OPEN ANKLE DISLOCATIONS

The Emergency Physician occasionally reduces open ankle dislocations if neurologic and/or vascular compromise of the foot is present and an Orthopedic Surgeon is not immediately available. Copiously irrigate the wound with sterile saline before attempting the reduction. The technique to reduce an open ankle dislocation is the same as that for a closed ankle dislocation.

ALTERNATIVE TECHNIQUE

A technique was developed by an Orthopedist and should be considered by the Emergency Physician if they do not have an assistant (**Figure 111-8**).²⁰ It is well described and worth trying. The Emergency Department has plenty of assistants who can help, including the nurse monitoring the patient. Consider this technique if the Emergency Department is busy and understaffed.

Place Kerlix gauze or stockinette as a sling behind the patient's knee (**Figure 111-8A**). Pull the gauze to flex the hip to 90° or more (**Figure 111-8B**). Tie the gauze to the gurney to maintain the patient's leg in this position. Use 2 inch gauze or stockinette and tie it into a loop. Slip the tied material between the first two toes (**Figure 111-8C**). Pull the end of the loop over the toes and secure it over toes 1 and 2 (**Figure 111-8D**). Lift the foot and ensure the gauze is secure (**Figure 111-8E**). Hang the gauze over an IV pole and hang the foot (**Figure 111-8F**).

Reduce the ankle dislocation as described above. Apply Webril (**Figure 111-8G**) followed by a splint (**Figure 111-8H**) to the extremity. Cut down the extremity after the splint is applied and hardened.

ASSESSMENT

Verify and document the neurologic and vascular status of the foot before and after any attempts at reduction.²¹ Any diminution or the absence of normal neurologic or vascular signs requires emergent consultation with an Orthopedic Surgeon.

AFTERCARE

Splint the extremity (Chapter 113). Apply a three-sided short leg splint from the base of the toes to just below the knee for posterior, lateral, and superior ankle dislocations that have been reduced. Immobilize the ankle in 90° of flexion and in a neutral position with respect to inversion and eversion.¹² Immobilize the reduced anterior ankle dislocation with the ankle in slight plantarflexion. The limb should be elevated, not bear weight, have frequent neurologic and vascular checks, and have frequent assessments for the development of the signs associated with a compartment syndrome.¹²

COMPLICATIONS

Most complications occur from the dislocation or fracture-dislocation and not the reduction procedure. This includes neurologic damage, vascular damage, and compartment syndromes. A posttraumatic peroneal tendon dislocation can occur and may be initially unrecognized. The patient usually becomes symptomatic after the acute stage when the tendon subluxes and dislocates. There is a low rate of

FIGURE 111-8. The one-person technique to care for a dislocated ankle. **A.** Gauze is placed behind the patient's knee. **B.** The hip is flexed and the gauze is tied to the gurney. **C.** Place looped 2 inch gauze between the first two toes. **D.** Pull the end of the loop over the toes and secure it. **E.** Lift the foot and ensure the gauze is secure. **F.** Hang the gauze over an IV pole, hang the foot, and reduce the ankle dislocation. **G.** Apply Webril. **H.** Apply the splint.

subsequently developing avascular necrosis and degenerative joint disease with isolated ankle dislocations.

Complications associated with the reduction procedure, if they occur at all, are usually neurologic and vascular injuries. These structures may become impinged in the relocated joint or on a fracture fragment. **Emergently consult an Orthopedic Surgeon if there is any diminished or absent function of any nerve or artery.**

The ankle might not be reducible. Interposition of bony fragments, foreign bodies, ligaments, nerves, tendons, and vasculature can occur in the ankle joint. Inadequate anesthesia can also be a

reason the dislocation is not reducing. Repeated attempts at reducing the dislocated joint can cause additional injury to the soft tissues, make a closed dislocation into an open dislocation, or cause a fracture. Consult an Orthopedic Surgeon and consider reduction in the Operating Room under general anesthesia.

SUMMARY

Ankle dislocations without fractures are uncommon yet serious injuries. Closed ankle dislocations can be reduced emergently and successfully with the use of procedural sedation. Open ankle dislocations should be irrigated in the Emergency Department and reduced rapidly after consultation with an Orthopedic Surgeon. Reduction, irrigation, and debridement are all likely to occur in the Operating Room if an Orthopedic Surgeon is immediately available. Any ankle dislocation with evidence of distal neurovascular compromise should be reduced immediately. All patients with ankle dislocations should have an Orthopedic Surgery consultation. Most closed ankle dislocations are managed nonoperatively with good long-term results.

Common Fracture Reduction

Christopher A. Gee

INTRODUCTION

Extremity fractures are common injuries and often necessitate an Emergency Department (ED) visit. Most closed fractures can be managed conservatively in the ED with splinting and follow-up if there is no neurologic or vascular compromise. This chapter addresses four common fracture patterns of the upper extremity that may require reduction by the Emergency Physician (EP). These include clavicular fractures, dorsally angulated distal radius or Colles fractures, displaced surgical neck fractures of the humerus, and supracondylar fractures of the humerus. **The reduction of fractures in the ED should involve consultation with an Orthopedic Surgeon prior to performing the procedure. The only exception to this is the existence of neurologic or vascular compromise and the Orthopedic Surgeon is not immediately available.**

CLAVICULAR FRACTURES

INTRODUCTION

Clavicular fractures are common and represent approximately 5% of all fractures.¹⁻⁴ Most of these occur at the junction of the middle and distal third of the clavicle, just medial to the coracoclavicular ligament. The clavicular fracture is the most common fracture encountered in childhood and occurs most often from a fall.⁴ These fractures are usually detectable clinically (**Figure 112-1**) with plain radiographs (**Figure 112-2**) helping to confirm the diagnosis.⁵ These fractures are relatively common and have a definite risk of associated complications.

ANATOMY AND PATHOPHYSIOLOGY

The clavicle is the only bony attachment of the upper extremity to the axial skeleton. It serves as a strut to support the shoulder girdle. It provides support and stabilization of the upper limb while allowing a broad range of movements. The clavicle is securely attached at both the acromioclavicular and sternoclavicular joints by ligaments

FIGURE 112-1. Middle third clavicle fracture with soft tissue swelling. (From Sherman SC, et al: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014. Courtesy of Northwestern Emergency Medicine teaching file with permission.)

FIGURE 112-2. Radiograph of a clavicle fracture. (Used from Kin412CF from www.commonswikimedia.org.)

(**Figure 112-3**). The subclavian vessels and nerves of the brachial plexus pass posterior and inferior to the clavicle at its midportion where it overlies the first rib. The proximity of these neurovascular structures and the underlying lung accounts for most of the potential complications of clavicular fractures.

The most commonly used classification for clavicular fractures was proposed by Allman.⁶ This simple classification is useful clinically and mechanistically but it does not predict outcomes. Group I fractures are midclavicular and account for approximately 80% of clavicular fractures. These most often result from a shearing force applied to the lateral aspect of the shoulder. Group II fractures involve the distal third of the clavicle and account for approximately 15% of all clavicular fractures. These most often result from a direct blow to the top of the shoulder. Several additional subclassifications have been proposed for these fractures based on the location of the fracture and associated ligamentous injury (e.g., Neer's classification recognizes the importance of the coracoclavicular ligaments in providing support to distal clavicle fractures).⁷ Operative repair is suggested for some of these subtypes. Refer all distal clavicular fractures for follow-up within 5 to 7 days to an Orthopedic Surgeon.^{1,2} Group III

FIGURE 112-3. The clavicle serves as a strut between the torso and upper extremity. The brachial plexus and great vessels pass behind the middle third of the clavicle.

fractures represent about 5% of clavicular fractures and involve the proximal third of the clavicle. They often result from a direct blow to the chest.

Patients with clavicular fractures are easily identified clinically. The clavicle is almost entirely subcutaneous and allows most displaced fractures to be palpated. Presenting signs and symptoms include ecchymoses, edema, and localized pain. Physical examination findings include superior and posterior displacement of the proximal portion of the clavicle due to traction from the sternocleidomastoid muscle (**Figures 112-1 and 112-4**). The shoulder is often displaced inferiorly by the weight of the upper extremity and medially by traction from the pectoral and the latissimus dorsi muscles. This position is protective for the patient but can exacerbate fracture displacement and overlap.

Most fractures are readily identifiable on standard anteroposterior radiographs (**Figure 112-2**). Some group II and III fractures may not be readily identifiable.¹ Additional views at a 45° angle cephalad (i.e., apical lordotic view) or 15° angle posteroanterior may be useful to assess displacement.^{1,3,8} Evaluation of the fracture by computed tomography (CT) may be necessary to confirm a clinically suspected fracture or to fully evaluate the degree of displacement. CT is usually required for adequate visualization of medial-end fractures extending into the sternoclavicular joint.⁹ Special views (i.e., cone views, tomograms, and upper rib films) may be helpful and are best determined in consultation with an Orthopedic Surgeon.

Clavicular injury and pain in children present two concerns. Nondisplaced greenstick fractures to the clavicle may not be radiographically visible for 7 to 10 days.^{2,3} Clinical suspicion of a clavicular fracture with a negative radiograph should prompt conservative management (i.e., rest, sling, icing, and pain control). Arrange follow-up for 7 to 10 days after the injury to obtain repeat radiographs. It may be unclear if the physes are involved in some group II and III fractures.^{2,3} **Any fracture through the physis requires an urgent referral to an Orthopedic Surgeon.**

INDICATIONS

Most clavicle fractures are treated nonoperatively. Reduction of clavicular fractures is necessary in a few circumstances. **It is required if neurologic and/or vascular compromise is present in the affected extremity.** This includes medial fracture displacement producing superior mediastinal compromise (e.g., aerodigestive tract compression, head vascular compression, or neck vascular compression). Make an emergent attempt at closed reduction.^{8,10} **Tenting of the skin by fracture fragments has the potential to convert a closed fracture to an open injury.** Manipulate or repair the fracture in the Operating Room. Reduce distal clavicular fractures that are significantly displaced. Reduction is otherwise optional and at the discretion of the treating physician.

Refer patients actively involved in competitive athletics or who have jobs that require overhead use of their arms (e.g., painters) for possible operative reduction by an Orthopedic Surgeon. Recent evidence has reversed trends to treat all clavicle fractures nonoperatively.^{4,11-13} Up to 20% of sports-related clavicle fractures are treated with surgery.¹⁴ Research has shown that athletes and workers with overhead jobs may get back to play or work sooner with surgical treatment.¹⁵ This is particularly true with complete displacement, comminution, or over 2 cm of shortening.¹⁵

CONTRAINDICATIONS

Reduction of most clavicular fractures is not usually necessary in either the pediatric or adult patient.^{1,2} A sling for simple arm support provides results comparable to the figure-of-eight harness without the risk of brachial plexus injury or patient discomfort.¹⁻³

FIGURE 112-4. Displacement of the clavicle and shoulder after a clavicular fracture. The clavicular head of the sternocleidomastoid muscle displaces the proximal clavicular fragment superiorly and posteriorly (1). The pectoralis major and latissimus dorsi muscles pull the shoulder medially (2). The force of gravity displaces the distal clavicle and shoulder inferiorly (3).

The sling may be additionally supported by a swath (**Figure 112-5A**) or a Velpeau wrap (**Figure 112-5B**). The Velpeau wrap is a sling-and-swath technique that positions the forearm diagonally rather than horizontally (**Figure 112-5B**). The Velpeau wrap has no practical advantages over a sling and swath.

Many physicians still prefer the use of a figure-of-eight harness (**Figures 112-5C, 112-5D, and 112-5E**). The figure-of-eight harness still represents the treatment of choice in patients over the age of 10 years in the presence of greatly displaced fragments.^{2,3} There is no evidence that the figure-of-eight harness offers any advantage over a simple sling for midclavicular fractures. Some patients may not tolerate a figure-of-eight harness initially due to the pain of the harness crossing the fracture line, but it may provide more usability of the extremity with time.¹⁶ The rates of compression of the neurovascular bundle, axillary pressure sores, and nonunion are higher in patients treated with the figure-of-eight harness.^{8,9}

Contraindications to the reduction of a clavicular fracture include other injuries that represent a threat to life or limb. The patient's airway, breathing, and circulation must first be addressed and stabilized. Patients with open clavicular fractures require emergent consultation with an Orthopedic Surgeon, intravenous antibiotics, and hospital admission for possible open reduction and internal fixation. Reduction is also contraindicated if an expanding hematoma, indicative of a vascular injury, is observed. Unfamiliarity with the reduction technique is a relative contraindication.

EQUIPMENT

- Figure-of-eight harness
- Sling
- Swath
- Kerlix rolls
- Elastic bandage

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Consider the administration of oral, intramuscular, or intravenous analgesics for patient comfort during the procedure. Procedural sedation (Chapter 159) is not required for this fracture reduction.

TECHNIQUE

Sit the patient upright on the side of the stretcher with their feet on the floor. Alternatively, the patient may be standing upright. Stand behind the patient. Grasp and pull both of the patient's shoulders backward as if the patient were standing at attention. Alternatively, this can be performed from the front with the patient's back against a corner. Instruct an assistant to apply the figure-of-eight splint while the patient is in this position. Apply the harness like a backpack and tighten the harness (**Figures 112-5C, 112-5D, and 112-5E**). **Reassess the neurologic and vascular integrity of the affected extremity after applying the harness.**

ASSESSMENT

Assess the neurologic and vascular integrity of the upper extremity for all patients initially, following any reduction attempts, and after the application of a figure-of-eight harness. Any noted neurologic and/or vascular compromise requires the removal of the harness. Reassess the neurologic and vascular integrity. Any residual neurologic and/or vascular compromise requires an emergent consultation with an Orthopedic or Vascular Surgeon.

AFTERCARE

Refer patients with uncomplicated fractures to an Orthopedic Surgeon in 7 to 10 days. Patients with group II distal fractures and

FIGURE 112-5. Treatment of clavicular fractures. **A.** Sling-over-swath immobilization. **B.** Velpeau sling immobilization. **C.** Anterior view of the figure-of-eight harness. **D.** Posterior view of the figure-of-eight splint. **E.** Photo of the figure-of-eight harness on a patient. (Used with permission from Sherman SC, et al: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014.)

any fracture in a child potentially involving the physis should have an urgent consultation with an Orthopedic Surgeon within 48 to 72 hours. Any patient with neurologic or vascular compromise, a pneumothorax, or signs of vascular injury from a clavicle fracture should be stabilized and admitted to the hospital after an emergent consultation with an Orthopedic Surgeon.

Discontinue the sling and encourage normal activities as pain allows. Instruct the patient to begin self-administered range-of-motion exercises (e.g., shoulder pendulums and “sawing” motion to prevent loss of glenohumeral mobility). Recovery of the range of motion of the shoulder is usually swift. Supervised physiotherapy is rarely required.¹⁰

General principles of orthopedic care are recommended. These include the application of ice, rest, nonsteroidal anti-inflammatory drugs, and narcotic analgesics. Most patients find the figure-of-eight

harness difficult to apply, extremely uncomfortable, and remove it shortly after its application. It is better tolerated after acute pain has improved. If the patient tolerates the harness, it should be tightened daily to ensure a shoulder back “at attention” posture. The figure-of-eight splint should be worn until there is evidence of clinical union and the arm can be abducted without pain. This generally requires 3 to 5 weeks in children and 6 or more weeks in adults.^{1,2} It may be more advantageous to apply a sling and swath or a sling and Velpeau wrap for patient comfort and compliance early on (Figures 112-5A and 112-5B). The outcomes of applying a figure-of-eight harness versus a sling are equivalent.^{17,18}

The sling is used to immobilize and support the elbow, forearm, and hand. They are simple, inexpensive, and effective. **It is imperative that the sling not be too short to allow the wrist and hand to hang over the sling.** This can result in an ulnar nerve neuropathy.

The addition of a swath to a sling is used to immobilize dislocated shoulders that have been reduced and proximal humeral fractures (**Figure 112-5A**). The swath immobilizes the humerus against the torso to limit motion at the shoulder. A shoulder immobilizer may be substituted for a sling and swath.

COMPLICATIONS

Complications of the reduction procedure include injuries to the brachial plexus, subclavian artery, and subclavian vein.^{1,2} These are usually the result of the initial injury and not the reduction procedure. **It is imperative to perform a neurologic and vascular examination before and after any attempt at reducing a clavicular fracture. Any neurologic or vascular deficit requires an immediate consultation with an Orthopedic or Vascular Surgeon.**

SUMMARY

Clavicular fractures are common, easily diagnosed, and often treated conservatively in the ED. Fractures of the distal or medial third may be more challenging. The incidence of complications is low. A thorough examination for associated injury is required. Any evidence of neurologic, vascular, or aerodigestive compromise requires an emergent consultation with an Orthopedic Surgeon.

DISTAL RADIUS COLLES FRACTURE

INTRODUCTION

A Colles fracture is an eponym for a transverse fracture of the distal radial metaphysis with dorsal displacement and angulation of the distal fragment.^{19,20} The fracture usually occurs 2 cm from the distal end of the radius (**Figures 112-6, 112-7, and 112-8**). The most common mechanism producing a Colles fracture is a fall on an outstretched hand.^{21,22} Most fractures occur in patients 50 years of age and older.^{21,22} This fracture is more commonly seen in women than in men.

The Colles fracture is the most common fracture of the wrist.^{21,22} Familiarity with its presentation, indications for reduction, and method of reduction are essential. Consult an Orthopedic Surgeon as these patients will need long-term follow-up and care. This is important due to the high incidence of long-term complications that may result, even when these fractures are managed and reduced appropriately.^{21,22}

FIGURE 112-6. Classic “dinner fork” deformity of a Colles fracture. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill, 2016. Photo contributor: Kristin L. Stevens, MD.)

FIGURE 112-7. The Colles fracture. **A.** The dinner fork deformity. **B.** Anteroposterior view. **C.** Lateral view.

ANATOMY AND PATHOPHYSIOLOGY

The distal radius is involved in two important articulations. First is the distal radioulnar joint which in conjunction with the proximal radius is responsible for pronation and supination of the forearm. The second is the wrist articulation. The distal radius normal anatomy can be remembered using the 11, 11, 22 rule. The radial length relative to the ulna should be 11 mm. The radius should have a volar tilt of approximately 11°. The radial inclination (i.e., degree of ramp up from ulnar side) should be approximately 22°. There are variances to this rule, but these numbers work as a target for reduction. **It is important to maintain the anatomic position of the distal radius with the reduction of a Colles fracture so that the patient retains good function of the wrist and distal radioulnar joints.**²²

A Colles fracture can be associated with several other significant injuries. Up to 60% of patients have a fracture of the ulnar styloid process.^{21,22} Other injuries include carpal fractures, distal radioulnar joint subluxations, flexor tendon injuries, median nerve injuries, ulnar neck fractures, and ulnar nerve injuries. A thorough physical

FIGURE 112-8. Radiograph of a Colles fracture. Views include the anteroposterior (left), lateral (middle), and Oblique (right). (Used from Ashish j29 from www.commonswikimedia.org.)

FIGURE 112-9. Clinical photo of a Smith fracture. (Used with permission from Sherman SC, et al: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014.)

examination and evaluation of the radiographs will uncover these injuries. **The forearm is effectively a ring structure, and a fracture at one location can result in a fracture or dislocation at a distal site.**

Standard radiographs include the anteroposterior and lateral views of the wrist (**Figure 112-8**). The Colles fracture is classically described as a “dinner fork” deformity when seen on lateral view (**Figures 112-6, 112-7A, and 112-8**). Intraarticular involvement with the fracture is rare and should prompt an emergent consultation with an Orthopedic or Hand Surgeon for reduction.²²

A variation of the Colles fracture is the Smith fracture or the reverse Colles fracture (**Figure 112-9**). A Smith fracture is like a Colles fracture except that the distal fracture fragment is displaced in a volar direction. This fracture most often results from a direct blow to the wrist while the hand is flexed. It is more commonly seen in young males. The management of these fractures is like that of the Colles fracture.

INDICATIONS

Nondisplaced distal radius fractures can be placed in a splint and the patient referred for follow-up with an Orthopedic or Hand Surgeon as an outpatient. Displaced fractures should be reduced.^{21,22} Simple Colles fractures may be reduced after consultation with an Orthopedic or Hand Surgeon. Some Orthopedic and Hand Surgeons prefer to reduce these fractures themselves often prior to open reduction and internal fixation. **The fracture must be emergently reduced if the patient has any neurologic and/or vascular compromise and the Orthopedic or Hand Surgeon is not immediately available.** The goal is to relieve the neurologic and/or vascular compromise. Ideal positioning is the goal but is not required as the Surgeon can later reduce any nonanatomic bony defect.

CONTRAINDICATIONS

Contraindications to the reduction of a Colles fracture include other injuries that represent a threat to life or limb. Airway, breathing, and circulation must first be addressed and stabilized. An Orthopedic or

Hand Surgeon should reduce any fractures that involve the radioulnar or wrist joint. Complex, comminuted, or open fractures require reduction by an Orthopedic or Hand Surgeon. Unfamiliarity with the reduction technique is a relative contraindication.

Any patient presenting with a Colles fracture should be evaluated for the presence of a compartment syndrome (Chapter 93). **Any suspicion of a compartment syndrome necessitates having intracompartmental pressures measured (Chapter 93). Elevated compartmental pressures require an emergent consultation with an Orthopedic, Hand, or General Surgeon.** Reduction and fasciotomies (Chapter 94) should be performed in the Operating Room.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution, 1% to 2% lidocaine
- 10 mL syringe
- 18 gauge needle
- Finger trap
- Compressive cotton bandage (e.g., Webril)
- Elastic wrap
- 8 to 10 pounds of weights
- Casting material (e.g., plaster, fiberglass, or prepackaged splints)
- Analgesia or procedural sedation supplies (Chapter 159)
- Ultrasound or fluoroscope

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record.

The patient should be given adequate analgesia for the procedure. This can often be accomplished with a hematoma block (Chapter 155).²³⁻²⁵ The procedure is briefly described here. Clean the skin overlying the fracture of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Place a subcutaneous wheal of local anesthetic solution over the area of the fracture hematoma. Insert an 18 gauge needle attached to a 10 mL syringe containing local anesthetic through the anesthetized skin and into the fracture hematoma. The entry site may need to be proximal from the fracture and the needle angled into the hematoma. Aspirate blood from the hematoma site to confirm proper needle placement. Inject 5 to 10 mL of the local anesthetic solution into the hematoma surrounding the fracture. Although a hematoma block will provide adequate analgesia in most patients, it may be incomplete. Adjunctive or alternative anesthesia includes intramuscular analgesics, intravenous analgesics, regional nerve blocks (Chapter 156), intravenous regional anesthesia (Chapter 157), and procedural sedation (Chapter 159).²⁶

TECHNIQUE

Place the patient supine on a stretcher. Perform a hematoma block as described above. Provide supplemental analgesia to the patient if required. Position the patient (**Figure 112-10A**). Abduct the arm 90° and allow it to hang over the edge of the bed. Flex the elbow 90° with the hand pointing upright. Insert the thumb, index finger, and long finger into the finger trap (**Figure 112-10B**). Suspend 8 to 10 pounds of weights from the distal humerus (**Figures 112-10C and 112-10D**). Allow the patient to remain in this position for 10 to 20 minutes to distract and disimpact the fracture fragments.

FIGURE 112-10. Patient positioning for the reduction of a Colles fracture. **A.** The arm is abducted 90° and the elbow is flexed 90°. **B.** The thumb, index finger, and long finger are placed in the finger trap. **C.** Weights are suspended from the distal humerus. **D.** Clinical photo. (Photo courtesy of Instrument Specialists Inc., Boerne, TX.) **E.** Using a loop of stockinette. (Used with permission from reference 27.)

This alone will often improve fracture alignment significantly. A loop of stockinette can be used if no weights are available (**Figure 112-10E**).²⁷

The fracture reduction involves traction followed by manipulation of the distal radial fragment to reverse the action that resulted in the fracture (Figure 112-11). Place both hands around the patient's wrist with the thumbs at the base of the fracture site (**Figure 112-11A**). Displace the fracture fragment distally with your thumbs while maintaining traction with the finger trap and

the weights (**Figure 112-11A**). Firmly grasp the distal fragment with your thumbs over the fracture site. Accentuate the deformity by bending more dorsally and then swing the distal fragment back into position while applying traction. This maneuver allows the distal fragment to become free from any contacts with the proximal radius which may prevent its movement. The wrist should look normal and the dorsal radius should feel flat. Don't let the normal bump of Lister's tubercle throw you off! Ultrasound or fluoroscopy can be

FIGURE 112-11. Reduction of a distal radius fracture. **A.** Proper positioning of the EP's hands. The arrows represent the application of a distally directed force. **B.** Application of an ulnar-directed force to reduce the radial deviation. **C.** The application of a splint to an unstable fracture. The finger trap and weights remain during the splinting.

used to verify reduction. Continue to manipulate the fragment distally while simultaneously manipulating it in a volar direction until the fragment assumes the proper anatomic position.

In the case of a volar angulation or Smith fracture, these manipulations would simply be reversed to reduce the displacement. Slight ulnar deviation of the fragment is often necessary (**Figure 112-11B**). Remove the weights. Palpation of a smooth surface at the radial and dorsal aspects of the radius indicates an appropriate reduction. Remove the finger trap and apply a splint.

Immobilize the forearm with a sugar tong splint. Place the forearm in a neutral position, halfway between pronation and supination. Place the wrist in 15° to 20° of flexion and 20° of ulnar deviation. Unstable fractures are best splinted immediately after the reduction while the hand is still maintained in the finger trap for traction (**Figure 112-11C**). Alternatively, the EP can maintain reduction while an assistant places the splint. **If a long arm cast is applied, be sure to bivalve it to prevent complications.** A short arm splint or cast may be used if the fracture is stable and impacted or is stable in an elderly person who needs to maintain mobility of the elbow.

ASSESSMENT

All patients should be assessed initially and following any reduction attempts for neurologic and vascular integrity of the extremity.²⁸ Obtain postreduction radiographs to confirm proper bony positioning. The procedure may be repeated if the radiographs show an incomplete reduction. Bedside ultrasound is a reliable and convenient method of assessing the reduction.²⁹⁻³¹ It is noninvasive, does not use ionizing radiation, involves minimal contact, and does not require the patient to remain motionless.³²

The goal is the restoration of the normal relationships and angles of the radius with congruity of the radiocarpal and radioulnar joints. Remember the 11, 11, 22 rule. The radial length relative to ulna should be 11 mm. The radius should have a volar tilt of approximately 11°. The radial inclination (i.e., degree of ramp up from ulnar side) should be approximately 22°.

Positioning is not critical if the reduction was performed for neurologic and/or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery. The Orthopedic or Hand Surgeon can later reduce the bony defect that remains.

AFTERCARE

Patients with uncomplicated or nondisplaced fractures should be referred to an Orthopedic or Hand Surgeon within 5 to 7 days. Patients with unstable fractures should be evaluated within 24 to 48 hours. **All patients should be given written instructions regarding the signs and symptoms of the splint or cast being too tight or a potential compartment syndrome.** Any patient with an open fracture, evidence of neurologic and/or vascular compromise, or suspicion of a compartment syndrome should be admitted to the hospital after an emergent consultation with an Orthopedic or Hand Surgeon.

General principles of orthopedic care are recommended. These include rest, elevation of the arm, nonsteroidal anti-inflammatory drugs, and narcotic analgesics. Instruct the patient to exercise the fingers and shoulder to prevent weakness, muscular atrophy, and the ligaments surrounding these joints from becoming taut.

COMPLICATIONS

Complications of the reduction procedure include postreduction edema and bleeding into the forearm. These may contribute to the development of a compartment syndrome. A neurapraxia of the median nerve is infrequent but possible. **Most complications result from the injury that produced the fracture and underlie the need for a good neurologic and vascular examination prior to any attempts at reduction.**²⁸ Any diminished or absent neurologic or vascular function requires an emergent consultation with an Orthopedic or Hand Surgeon. Incomplete reduction can result in future morbidity (e.g., pain, decreased range of motion, and deformity).

SUMMARY

A dorsally displaced distal radius or Colles fracture is the most common fracture of the wrist. Familiarity with its presentation and the method of reduction are essential. Some Orthopedic and Hand Surgeons prefer to reduce these fractures. Consultation is advised prior to reduction unless the extremity has evidence of neurologic or vascular compromise. These fractures have a high incidence of long-term complications, even when appropriately managed and reduced.^{21,22}

DISPLACED SURGICAL NECK FRACTURE OF THE HUMERUS

INTRODUCTION

Proximal humeral fractures are relatively common, approximately 5% of injuries to the appendicular skeleton (**Figures 112-12 and 112-13**).³³ Most patients presenting to the ED with a proximal humeral fracture are elderly and usually have osteoporosis. The most common mechanism of injury involves a fall on an outstretched hand with the elbow extended.^{3,33} The EP can manage most of these fractures conservatively.³³ The EP must have a basic knowledge of the types of proximal humeral fractures, particularly those that should be managed by the Orthopedic Surgeon, and the indications for emergent reduction.

ANATOMY AND PATHOPHYSIOLOGY

The proximal humerus is composed of the articular segment, the greater and lesser tuberosities, and the proximal humeral shaft. This anatomic division is based on the physeal lines and the development of the humerus.^{2,3,33} The commonly used Neer classification uses the observation that proximal humeral fractures separate primarily along these physeal lines.^{2,3,33} It is the displacement of fragments, not the total number of fracture lines, that is important. Significant displacement is considered to be a separation of greater than 1 cm,

FIGURE 112-12. Surgical neck fracture of the humerus. (Used with permission from Sherman SC, et al: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014.)

FIGURE 112-13. Radiograph of a displaced surgical neck fracture of the humerus. (Used with permission from Sherman SC, et al: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014.)

angulation of more than 45°, or displacement of the greater tuberosity greater than 0.5 cm.^{3,33} The Neer classification separates fractures into one-part to four-part fractures. Approximately 80% of proximal humeral fractures are one-part or minimally displaced fractures.^{3,33} These fractures can be managed conservatively. Multiple-part fractures often require surgical intervention by an Orthopedic Surgeon. **A surgical neck fracture of the humerus is the only proximal humeral fracture that should be reduced by the Emergency Physician.** These can be difficult fractures to get back into anatomic alignment as the fragments may be oblique or transverse and slide off one another. The purpose is to get the fragments into acceptable displacement and angulation and not perfect anatomic alignment.

INDICATIONS

Surgical neck fractures of the humerus may be reduced in the ED after consultation with an Orthopedic Surgeon. **The reduction should be undertaken emergently after consultation with the Orthopedic Surgeon and if they are not immediately available if the patient has neurologic and/or vascular compromise.**

CONTRAINDICATIONS

Contraindications to the reduction of humeral fractures include other injuries that represent a threat to life or limb. Airway, breathing, and circulation must first be addressed and stabilized. An Orthopedic Surgeon should manage any open fracture, complex comminuted fracture, or multiple-part fracture as the patient often requires operative repair and reduction.^{2,3,33} Unfamiliarity with the reduction technique is a relative contraindication. Children presenting with separation of the proximal humeral epiphysis require meticulous realignment. These fractures should be reduced by an Orthopedic Surgeon.²

FIGURE 112-14. Reduction of a displaced surgical neck fracture of the humerus. **A.** The application of distal traction to the elbow. **B.** Lateral pressure is applied to reduce the fracture while maintaining distal traction, adducting the elbow, and slightly flexing the arm.

EQUIPMENT

- Supplies and equipment for procedural sedation (Chapter 159)
- Compressive cotton bandage (e.g., Webril)
- Casting material (e.g., plaster, fiberglass, or prepackaged splints)
- Sling
- Elastic wrap

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Adequate anesthesia for this procedure is best accomplished with procedural sedation (Chapter 159). Obtain an informed consent for the procedural sedation procedure.

TECHNIQUE

Place the patient supine. Perform procedural sedation (Chapter 159). Completely flex the patient's elbow. Apply a distractive force along the long axis of the humerus by applying traction on the patient's elbow (**Figure 112-14A**). Simultaneously slightly adduct the arm across the chest to allow relaxation of the pectoralis muscle, slightly

flex the arm, and apply lateral pressure to the fracture site while distracting the humerus (**Figure 112-14B**). Slowly release the traction on the elbow as the fragments come into good reduction.

Apply a sugar tong coaptation splint from over top of the shoulder, laterally down the upper arm, under the elbow, and back up into the axilla (**Figure 112-15A**). A trick to helping this splint stay in place is to put the splint material into a tube gauze and cut strips into the ends of the gauze. Then tie the upper end around the patient's neck and the other end around the top of the shoulder to keep the splint in place. Secure the splint in the usual manner with an elastic wrap. Apply a sling (**Figure 112-15B**). Place the arm slightly across the chest and apply a sling and swath in the event of an unstable proximal humeral fracture (**Figure 112-5A**). This can help to limit the pull of the pectoralis muscle on the fracture site. Don't tighten the sling too much as the weight of the arm and splint will help to pull on the fracture and correct any residual misalignment.

ASSESSMENT

All patients should be assessed both initially and following any reduction attempts for neurologic and vascular integrity of the extremity. Obtain postreduction radiographs to confirm proper bony positioning. The procedure may be repeated if the radiographs show incomplete reduction.

FIGURE 112-15. Immobilization of the reduced surgical neck fracture of the humerus. **A.** Application of a sugar tong splint. **B.** A sling is applied after padding is placed between the upper arm and the thorax.

Positioning is not critical if the reduction was performed for neurologic or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery. The Orthopedic Surgeon can later reduce the bony defect that remains.

AFTERCARE

Patients with uncomplicated or nondisplaced fractures should be referred to an Orthopedic Surgeon in 5 to 7 days. **All patients should receive written instructions on the signs and symptoms of the splint being too tight or a potential compartment syndrome.** Patients with unstable fractures should be evaluated within 24 hours. Any patient with an open fracture, evidence of neurologic and/or vascular compromise, or suspicion of a compartment syndrome should be admitted to the hospital after an emergent consultation with an Orthopedic Surgeon.

COMPLICATIONS

Complications of the reduction procedure include primarily neurologic and/or vascular compromise. **Most complications result from the injury that produced the fracture. This underlies the need for a good neurovascular examination prior to any reduction attempt.**

SUMMARY

Proximal humeral fractures are common. The EP can manage most of these conservatively. A displaced surgical neck fracture is the only proximal humeral fracture that should be reduced in the ED. Reduction is often reserved for patients who have evidence of neurologic and/or vascular compromise. Most of these injuries require open reduction and internal fixation in the Operating Room by an Orthopedic Surgeon. Arrange close follow-up for any patient discharged from the ED along with good discharge instructions about any potential complications.

SUPRACONDYLAR FRACTURE OF THE HUMERUS

INTRODUCTION

Distal fractures of the humerus located within 2 cm or just proximal to the epicondyles are known as supracondylar fractures (Figures 112-16 and 112-17). Supracondylar fractures are classified as extension or flexion fractures.³⁴⁻³⁶ These fractures are common in children under the age of 15 and are rare in people over the age of 20.³⁴⁻³⁶ Supracondylar fractures are the most common elbow fractures seen in children.³⁷ The most common mechanism of injury involves a fall onto an outstretched hand with the elbow locked in extension.³⁴⁻³⁶ The same mechanism of injury in an adult often results in a posterior elbow dislocation. The bones of an adult are much stronger than those of a child, so that the ligaments rupture rather than the bone fracturing.^{34,35} **These injuries have a significant incidence of associated neurologic and/or vascular injury.³⁸ There is a significant incidence of a subsequent compartment syndrome.** Refer all supracondylar fractures to an Orthopedic Surgeon for follow-up care.

ANATOMY AND PATHOPHYSIOLOGY

The child will be holding the affected extremity with the elbow flexed 90° and the arm adducted.^{34,36} Localized tenderness, swelling, and the occasional deformity will be found upon examination. The patient may have a “pucker sign.”³⁹ Extension fractures have

FIGURE 112-16. Supracondylar fracture of the humerus. **A.** Anteroposterior view. **B.** Lateral view.

posterior displacement of the distal fragment of the humerus that is exacerbated by the pull of the triceps muscle.^{34,36} The posterior displacement of the olecranon may mimic a posterior elbow dislocation. **Anterior angulation of the sharp proximal fragment (Figures 112-16B and 112-17) may injure the brachial artery or median nerve (Figure 112-18).** **A thorough neurovascular examination is essential.** There will be loss of the normal olecranon prominence with flexion injuries. These fractures are frequently open and vascular injury is less frequent.^{34,36}

The modified Gartland classification of supracondylar humeral fractures is the most commonly accepted and used system.⁴⁰ A Gartland type I supracondylar fracture is nondisplaced or minimally

FIGURE 112-17. Radiograph of a supracondylar fracture. (Used with permission from Shah BR, et al: *Atlas of Pediatric Emergency Medicine*, 2nd ed. New York: McGraw-Hill; 2013. Photo contributors: Binita R. Shah, MD, and John Amodio, MD.)

FIGURE 112-18. Major neurologic and vascular structures crossing the elbow.

displaced by < 2 mm and is associated with an intact anterior humeral line. The anterior humeral line is a line drawn on a true lateral radiograph of the elbow down the anterior surface of the humerus. Its distal end should traverse through the middle third of the capitellum. Gartland type I fractures may only require a posterior long arm splint and no reduction.⁴¹⁻⁴³ Make this decision in conjunction with the consultant. A type II supracondylar fracture is displaced by > 2 mm and the posterior cortex is intact but may be hinged. The anterior humeral line does not go through the middle third of the capitellum. Type III fractures are displaced with no meaningful cortical contact. Gartland type IV fractures are characterized by an incompetent periosteal hinge circumferentially and are defined by instability in flexion and extension.⁴⁰ **The EP's role in a supracondylar humeral fracture is to ascertain whether there is any neurologic and/or vascular compromise of the extremity distal to the fracture.**

Radiologic evaluation of supracondylar fractures is best appreciated on the lateral view. One-quarter of these fractures in children are of the greenstick variety.^{34,36} The posterior fat pad sign is not visible on a normal elbow and indicates an effusion. Examine the radiograph for the posterior fat pad and anterior humeral line. Initial radiographs may show no evidence of a fracture except for a posterior fat pad sign.³⁷ Treat a child with localized tenderness in the supracondylar area without any radiologic signs of a fracture conservatively with splinting and referral to an Orthopedic Surgeon.^{34,36} The anteroposterior view allows an assessment of any medial to lateral displacement. Displaced fractures should be emergently reduced by an Orthopedic Surgeon.

INDICATIONS

The only indication for reducing a supracondylar fracture of the humerus emergently is if there is any neurologic and/or vascular compromise of the extremity distal to the fracture and an Orthopedic Surgeon is not immediately available.

CONTRAINDICATIONS

Contraindications to the reduction of a supracondylar fracture include other injuries that represent a threat to life or limb. The patient's airway, breathing, and circulation must first be addressed and stabilized. An Orthopedic Surgeon should manage any open or displaced fractures. Unfamiliarity with the reduction technique is a relative contraindication. Simple traction on the extended elbow may be sufficient to restore neurologic and/or vascular integrity if the EP is uncomfortable with the reduction procedure.

EQUIPMENT

- Supplies and equipment for procedural sedation (Chapter 159)
- Compressive cotton bandage (e.g., Webril)
- Elastic wraps
- Casting material (e.g., plaster, fiberglass, or prepackaged splints)
- Prepackaged splinting sheets
- Sling and swath

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Adequate anesthesia for this procedure is best accomplished with procedural sedation (Chapter 159). Obtain an informed consent for this procedure in addition to the reduction procedure.

TECHNIQUE

Place the patient supine. Perform procedural sedation (Chapter 159). Slightly abduct the affected extremity. Place the patient's hand in the midposition between pronation and supination with the thumb pointing upward (**Figure 112-19A**). Grasp the patient's elbow region with the dominant hand and grasp the wrist with the nondominant hand (**Figure 112-19A**). Instruct an assistant to stabilize the distal humerus (**Figure 112-19A**). Apply distal traction in line with the long axis of the arm by pulling on the wrist while simultaneously correcting any medial or lateral displacement at the elbow (**Figure 112-19A**). Supinate the patient's arm and correct any remaining medial or lateral displacement at the elbow while simultaneously distracting the wrist (**Figure 112-19B**). Place the thumb of the dominant hand across the joint line of the elbow with the fingers behind the olecranon process and slowly flex the elbow to just beyond 90° while distracting the elbow (**Figure 112-19C**). Splint the arm in this position. Avoid tight bandaging or splinting as significant swelling may occur up to 24 hours after the reduction. Excessive flexion or extension may compromise the limb's vascularity and increase compartment pressure.⁴⁴

ASSESSMENT

All patients should be assessed before and after any reduction attempts for neurologic and vascular integrity of the extremity. Postprocedural swelling is common. Obtain postreduction radiographs to confirm proper bony positioning. The procedure may be repeated if the radiographs show incomplete reduction.

Positioning is not critical if the reduction was performed for neurologic or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery. The Orthopedic Surgeon can later reduce the bony defect that remains.

FIGURE 112-19. Reduction of a supracondylar fracture. **A.** Positioning of the hands of the EP and the assistant. Distal traction is applied (arrow) while reducing the medial or lateral displacement (arrowheads). **B.** The patient's hand is supinated while maintaining distal traction (arrow). Any remaining medial or lateral displacement is corrected (arrowheads). **C.** The patient's elbow is flexed (curved arrow) just beyond 90° while maintaining distal traction (straight arrow).

AFTERCARE

Patients with supracondylar fractures should be admitted to the hospital to be monitored for a delayed compartment syndrome, neurologic compromise, or vascular compromise. Any patient with an open fracture, evidence of neurologic or vascular compromise, or suspicion of a compartment syndrome should be admitted to the hospital after an emergent consultation with an Orthopedic Surgeon.

COMPLICATIONS

Most complications result from the injury that produced the fracture and not the reduction.³⁸ Complications of the reduction procedure include primarily neurologic and vascular compromise. This is most often a neurapraxia and may involve any of the three nerves crossing the fracture. The neurovascular structures crossing the fracture may become lacerated or entrapped during the reduction. **The necessity of an accurate and complete neurovascular examination before and after any reduction attempts cannot be overemphasized.**

SUMMARY

Supracondylar fractures of the humerus are common in children under the age of 15 and rare over the age of 20 years. The most common mechanism of injury involves a fall onto an outstretched hand with the elbow locked in extension. These injuries have a significant

incidence of associated neurologic injury, vascular injury, and the subsequent development of a compartment syndrome. The only indication for the reduction of a supracondylar fracture of the humerus by the EP is neurologic and/or vascular compromise distal to the fracture.

Casts and Splints

Eric F. Reichman

INTRODUCTION

External immobilization of the extremities is the oldest form of fracture treatment. References to plaster use and various immobilization techniques are scattered throughout historical records. The use of plaster of Paris, also referred to as plaster, in fracture management dates back to the eighteenth century Turkish Empire. Plaster bandages became commercially available in 1931. Despite the development of plastic (i.e., fiberglass) casting products, the plaster bandage persists as the most economical and versatile material for immobilization techniques.¹

Immobilization of an injured extremity begins at the scene of the accident. According to Advanced Trauma Life Support guidelines, the injured extremity must be aligned and immobilized after the appropriate management of any life-threatening problems.² Prehospital immobilization of fractures is invaluable for pain control, prevention of soft tissue injury, prevention of any new or further injury to neurovascular structures, and management of edema. External immobilization with splinting or casting is often the definitive management of injured extremities in the Emergency Department. Knowledge and expertise in this therapeutic procedure are essential for any Emergency Physician.

Splints are commonly used for the immobilization of upper and lower extremity injuries. **A splint is a hard bandage that is not circumferential and prevents movement of the fracture site.** Splinting may be the definitive management of certain injuries. Splints have the distinct advantage of being quick and easy to apply, and they are designed to accommodate postinjury swelling. The major disadvantages of splints are that they provide slightly less rigid immobilization than casting and require an Orthopedic Physician visit within a few days to be replaced with a cast.

Casts, which are generally circumferential, are better suited for the definitive treatment of fractures and ligamentous injuries. Casts provide superb immobilization and allow for the maintenance of a reduced fracture. The rigidity of a cast limits the amount of swelling and soft tissue edema in the first 24 to 48 hours after the injury and is therefore associated with an increased risk of developing a compartment syndrome. **Casts should be used with caution in the management of acute fractures. They are often split (bivalved) to allow swelling and prevent the development of a compartment syndrome before the patient is discharged from the Emergency Department.**

ANATOMY AND PATHOPHYSIOLOGY

Casts and splints rely on the principle of a three-point mold to maintain fracture reduction (**Figure 113-1**). **When applying a cast or splint, the application of directed force to the underlying bones should be uppermost in one's mind.** To obtain a three-point mold, place one point of contact over the convex side of the fracture site. The other two points of force are aimed in an opposite direction, proximal and distal to the fracture, and from the concave side. This is the classic teaching of Sir John Charnley who noted that "a curved plaster is necessary in order to make a straight limb."³ A skin-tight cast that closely follows the contours of the extremity will not maintain the fracture in alignment as it does not apply appropriate pressure to the underlying bones.

Casts and splints also rely on hydraulic force to maintain limb length and alignment. One may think of the soft tissues surrounding the broken bones as constituting a flexible cylinder that contains the underlying fracture, hematoma, and edema. Axial loading of the bones will cause the soft tissue to expand and allow the limb to shorten. **A well-applied cast or splint will resist the outward**

FIGURE 113-1. Three points of force are acting on the injured extremity in a well-applied cast or splint. One force is applied to the convex side of the fracture site (1). Two opposing forces are applied at sites proximal and distal to the fracture and on the concave side of the fracture (2).

TABLE 113-1 Characteristics of Plaster and Fiberglass

	Plaster	Fiberglass
Allergic reaction	Almost none	Almost none
Clothes	Easily washes off	Resin permanently stains
Cost	Inexpensive	Expensive
Curing	48–72 hours	30 minutes
Moldability	Excellent	Good
Radiolucency	Poor	Good
Skin	Easily washes off	Resin bonds for days
Strength	Good	Excellent
Water resistance	Poor	Excellent
Weight	Heavy	Light

expansion from axial loading and provide additional support for the limb.⁴

Plaster is made of finely ground calcium sulfate that has been dehydrated by heat. The calcium sulfate is impregnated into muslin sheets containing dextrose or starch. The addition of various chemicals (e.g., alum, aluminum, copper, iron, magnesium, salicylic acid, or zinc) to the calcium sulfate alters the rate of hardening after the addition of water. Plaster grades include fast-setting and extra-fast-setting plaster, which are useful for different applications. Long cylindrical crystals form and interlock as the cast sets to give strength to the cast. **For this reason, plaster should not be moved once it begins to set as these crystals may fracture causing the plaster to lose strength. Careful lamination of the plaster while it is still wet will add strength by enabling the formation of longer crystals.**

Crystal formation during the setting of plaster is an exothermic process that is initiated by the addition of water to the plaster. Using warm water will accelerate the chemical reaction, harden or set the plaster sooner, and decrease the setting time. Unfortunately, the use of very warm or hot water will also increase heat production while the plaster sets. The use of very thick splints or fast-setting plaster will also increase the heat produced during setting. Use cold water to activate the plaster, increase the setting time, and decrease the heat produced during setting. **Great care should be taken if warm water is used in applying a cast or splint to an anesthetized patient, unconscious or altered patient, or an insensate limb.^{5,6} The setting plaster may burn the skin in these cases as the patient will not notice the heat and pain associated with the exothermic reaction.** Rubbing and working with the plaster will also accelerate the setting process.⁷

The same principles described above regarding plaster apply to the use of fiberglass. The fiberglass splinting material consists of cloth impregnated with a plastic, spun glass resin, and a water-activated catalyst. A comparison of plaster and fiberglass can be found in Table 113-1.

INDICATIONS

SPLINTS

An injured extremity should be splinted as soon as possible after the injury. Splinting results in the reduction of pain, reduction of edema, relief of pressure on neurovascular structures, and prevention of further soft tissue injury. Any available material can be used to immobilize or realign the affected extremity in the prehospital setting and in the Emergency Department. **A thorough neurologic and vascular examination of the extremity should be performed and documented before temporarily splinting the extremity.⁸ A thorough neurologic and vascular examination of the extremity should be performed and documented after temporarily splinting**

the extremity. The initial neurovascular examination, temporary splinting, and post-splinting neurovascular examination should be performed before the patient undergoes radiographic studies. Immobilize an extremity in the appropriate and definitive splint after diagnosing and stabilizing the fracture. A thorough neurologic and vascular examination of the extremity should be performed and documented after the placement of the definitive splint.

An extremity fracture is the most common reason for placement of a splint.⁹ A splint is also indicated following the reduction of a dislocated joint. The patient with ligamentous sprains or muscle strains will also receive significant pain relief with splint immobilization. Splints are placed following orthopedic or soft tissue surgery of the extremities.

CASTS

There are few reasons to immobilize an acutely injured extremity with a cast in the Emergency Department. Most injuries can be initially stabilized with a splint. Following reduction of certain fractures, placement of a cast will secure the bones in their proper alignment and allow for a primary union (e.g., distal radius or tibial shaft).^{10,11} **Placement of a cast instead of a splint should be performed only if the patient has access to close follow-up or can return to the Emergency Department for a cast check within 24 hours.**

Patients with casts may present to the Emergency Department with various cast-associated problems. The cast may have become wet and lost its strength and integrity. The cast may no longer fit properly if the affected extremity has decreased in size from reduction of swelling. The cast must be removed and the affected area examined if the patient complains of persistent pain.^{10,11} All these patients may safely be placed back in a cast. They may also be placed in an appropriate splint and follow-up arranged with an Orthopedic Surgeon for casting.

CONTRAINDICATIONS

SPLINTS

There are no absolute contraindications for the placement of a splint.⁹ Relative contraindications include soft tissue injuries or wounds that need regular care and evaluation. In this setting, the wounds should be appropriately dressed, padded, and the splint constructed so that it can easily be removed and replaced. A “window” may also be cut in the splint as it is being applied to facilitate access to the wound. The splint should not place pressure over the wound.

CASTS

Do not cast an extremity that has the potential for significant edema or that may develop a compartment syndrome. An injured extremity with significant edema or soft tissue injuries should not be constrained by a cast. Similarly, infections of joint spaces or soft tissues must remain exposed for frequent evaluations. Any fracture that is not adequately reduced by closed manipulation should not be placed in a cast.^{3,11} A cast should not be applied by someone unfamiliar with the technique and unable to manage the associated complications.

EQUIPMENT

- Bucket or basin to hold water
- Source of cool or tepid water
- Cotton cast padding (e.g., Webril), various widths

- Plaster strips or rolls, various widths
- Fiberglass strips or rolls, various widths
- Prefabricated splinting material, various widths
- Bias stockinette, various widths
- Cloth tape, 1 inch wide
- Bias stockinette, optional
- Elastic bandages (e.g., Ace wraps), various widths
- Slings, various sizes

The width of the cotton cast padding, plaster, and bias stockinette required will vary by the site of application. In general, 1 to 3 inch material can be used for the hands and digits, 3 to 4 inch wide material can be used for the upper extremity, and 4 to 5 inch wide material can be used for the lower extremity. Alternative materials include fiberglass strips and rolls instead of plaster strips. Elastic bandages (e.g., Ace wraps) can be substituted for bias stockinette. Prefabricated splinting material is also available, with the padding and fiberglass (or plaster) already assembled and covered with cotton material (e.g., Parker Splints or Orthoglass). **It is important to remember that all of the casts and splints described in this chapter can be constructed using plaster or fiberglass splinting material.**

Fiberglass rolls must be cut to the appropriate length with scissors whereas plaster can easily be torn by hand. The fibers are too strong to be torn by hand. Gloves should always be worn when handling fiberglass because the resin will stick to skin and is exceedingly difficult to remove.^{4,7,10} Otherwise, the same principles described for plaster apply to fiberglass.

PATIENT PREPARATION

Whether reducing a fracture or simply manipulating the extremity to place a cast or splint, make sure that the patient has received appropriate analgesia. Conduct a thorough examination of the skin overlying the site of injury. **It is inexcusable to miss the diagnosis of an open fracture. All skin wounds must be inspected and explored.** Exploration of the wound is undertaken cautiously with a sterile probe or gloved finger according to wound size. Fractures may puncture the skin from the “inside out,” resulting in an innocuous appearing pinhole in the skin. These are grade I open fractures, and they carry a 5% risk of infection.¹² Cover any open fractures with sterile saline-soaked gauze until formal irrigation and debridement can be undertaken in the Operating Room. Do not examine open wounds repeatedly due to the risk of increased contamination. Administer tetanus prophylaxis as indicated. Administer the appropriate intravenous broad-spectrum antibiotics for an open fracture if present.

Document a thorough neurologic and vascular examination of the injured extremity before and after any splinting or casting.⁹ A change in the neurologic or vascular status of an extremity may be the result of the fracture reduction, the splint or cast application, or a compartment syndrome. The fracture may have to be reduced and held in position while a splint or a cast is applied. If no reduction is needed, splint the affected extremity in a position of stability. Techniques for achieving and maintaining fracture reduction are beyond the scope of this chapter.

GENERAL SPLINTING CONSIDERATIONS

The general considerations and techniques common to the application of all splints are discussed in this section. It describes the techniques for splints using cotton cast padding, plaster, and bias stockinette. Many alternative materials are available and may be

substituted, such as fiberglass for plaster or elastic wraps for stockinette. Prefabricated splint materials that incorporate padding may also be used. The techniques described in these chapters are applicable for all splinting materials. Where alterations in technique are required, they are so noted.

Splints are constructed of cotton padding overlaid by splinting material (i.e., strips of plaster or fiberglass) and subsequently held in position by an overwrap of bias stockinette or an elastic bandage. Splint padding should be thick enough to provide protection for the skin from the plaster. **The splint or cast will be unable to provide sufficient immobilization of the fracture to maintain a reduction if the padding is too thick.** One to two layers of cotton cast padding are sufficient over the fracture site. Three to four layers of cotton cast padding are required at the proximal and distal extents of the splint to distribute the stresses. Thinner padding can be used when maintenance of fracture reduction is a priority (e.g., with a fracture of the distal radius).

Plaster strips are available in precut slabs measuring either 4 by 15 or 5 by 30 inches. The precut strips have the advantage of speed and ease of application. Alternatively, plaster and fiberglass are available in rolls of various widths ranging from 2 to 8 inches. The rolls of splinting material may be rolled out to the precise length desired and cut appropriately. The rolls of splinting material are useful for splints requiring long strips such as coaptation splints. **The ideal thickness for most upper extremity splints is 10 sheets or layers of plaster or 5 to 6 layers of fiberglass.¹³ The use of 15 sheets or layers of plaster or 8 to 10 sheets of fiberglass is preferable for lower extremity splints.** The strength of the splint depends on the number of layers as well as the lamination of the layers during their application.

A piece of cotton cast padding may be used as a template for the length of the required splinting material. Roll a piece of cotton cast padding over the desired location of the splint to determine the length of the splinting material required (**Figure 113-2A**). Roll out the splinting materials to the appropriate lengths and cut them slightly shorter than the template.

An alternative is to cut the splinting material approximately 1 to 2 inches longer than necessary so that the ends may be folded back on themselves. This will prevent any contact of the sharp splint ends with the patient's skin. Prefabricated splinting material covered with padding has jagged ends and once it has been cut it begins to harden immediately, even prior to the addition of water. These sharp ends will rub against the patient's exposed skin, even through cotton cast padding or bias, and for that reason, they should be folded back. To avoid premature hardening of the prefabricated splinting material, keep it inside of the protective foil and seal it with tape or the manufacturer-provided clips.

Bias stockinette may be applied to the extremity for extra padding and comfort. This may also be omitted depending on Physician preference. Prepare strips of cotton cast padding. **The strips of cotton cast padding should always be longer and wider than the plaster.** This prevents the plaster from touching the skin and causing a pressure sore, abrasion, or burn. Padding is especially important at the proximal and distal edges, as this is where significant pressure originates. Apply additional pieces of padding over pressure points and bony prominences (e.g., the olecranon). **Additional padding may also be created by folding a loose piece of cotton cast padding back on itself several times and placing it over the individual prominences.** Alternatively, cotton cast padding may be applied directly by wrapping the pressure point or bony prominence circumferentially as is done in cast application.

Begin applying the splint once the padding and splinting material have been cut to the appropriate lengths. Be sure that all required materials have been collected before dipping the splinting material

FIGURE 113-2. Preparing the splint. **A.** Cotton cast padding to measure the length of material needed. **B.** Plaster is submersed in tepid water with air bubbles arising from it. **C.** Fiberglass is submersed in tepid water with air bubbles arising from it. **D.** Suspend the lengths of wet splinting material over the bucket and squeeze out the excess water. **E.** The splinting material is placed on the cotton cast padding.

in water to activate it. Only a limited amount of time, less than 10 minutes, is available for splint application and molding once the splinting material is wet. Completely immerse all of the splinting material in a bucket of tepid, clean tap water. Keep the splinting material submersed until no more bubbles arise from under the water (**Figures 113-2B and 113-2C**). At this point, the splinting material can absorb no more water. Suspend the splinting material over the bucket and lightly squeeze out the excess water by running your fingers down its length (**Figure 113-2D**). **It should only take two or three passes of the fingers to remove the excess water. Do not wring the plaster strips like a dish rag, as that will cause loss of plaster into the bucket!** Lay the splinting material on a clean flat surface. Run your hands over the splinting material to laminate the individual strips into one slab. Laminating the strips together adds significant strength. Lay the splinting material onto the cotton cast padding (**Figure 113-2E**). Fold the edges of the cotton cast padding over the splinting material to cover all the edges completely. Apply the splint to the extremity.

An alternative and more commonly used method that is preferred by many is to apply the cotton cast padding circumferentially over the extremity, overlapping each layer by 50%, and then applying the wet splinting material. In this fashion, the splinting material will “stick” to the cotton cast padding. **Smooth the splinting material with the broad aspect of your hand and not your fingers to help minimize irregular indentations.**

The cotton cast padding should be facing the patient and no splinting material should directly contact the skin regardless of the method used. Secure the splint with a wrap of bias stockinette or an elastic bandage. The wrap must be applied under minimal tension when you are using an elastic wrap to affix the splint. The elastic may cause increasing pressure over time. Gently apply strips of tape to the end of the wrap to secure the bias stockinette or the elastic bandage. **Tape should never be applied circumferentially as this can impede expansion of the splint due to underlying swelling and create a tourniquet effect. Application of the tape under tension before the splint is completely hard will cause indentations in the splinting material and result in pressure points on the underlying skin.**

The splinting material may be molded at this point to achieve greater conformity to the extremity or better reduction of the fracture. **It is paramount to use only the palms and not the fingertips when molding the finished splint. Finger pressure induces deformity in the splint that will result in skin breakdown under those defects. All molding must stop once the splinting material begins to harden.** The plaster is quite fragile and cracks that weaken the splint may be propagated. Apply 1 inch wide tape in a spiral fashion to secure the bias or elastic wrap after the plaster has hardened.

If using prefabricated splinting materials, cut it to length, remove it from the sealed foil, and wet it to activate the splinting materials. Briefly pass the prefabricated splinting material under cool water. Place the wet prefabricated splinting material on a towel and roll it up. This will remove any excess water. **The splinting material should not be soaked or placed in a bucket of water. It requires only one pass under the running water.** The prefabricated splinting material should not be squeezed dry as this tends to deform the splinting material and results in a poorly molded final product.

Apply the splint and mold it to the extremity. **It is paramount to use only the palms and not the fingertips when molding the finished splint. Finger pressure induces deformity in the splint that will result in skin breakdown under those defects.** Any excess length of splinting material should be folded back on itself so that the cut ends do not come in contact with the patient's skin. **The distal part of any extremity should always be left visible so that the Emergency Physician may recheck a neurovascular exam.**

The patient will also be able to visualize any changes in color that may occur latter. It is held in place by circumferentially wrapping the splinting material with an elastic bandage. **The elastic bandage should be applied relatively loosely so it will not induce increased compartment pressures.**

GENERAL CASTING CONSIDERATIONS

The general considerations and techniques common to the application of all casts are discussed in this section.^{3,7,10,14} **Casting requires careful circumferential turns of material instead of longitudinal layers of material, as for splints.** Casts are constructed of cotton cast padding overlaid with either fiberglass or plaster bandages (i.e., casting materials). The four areas that require particular attention and are discussed in this section are the application of padding, padding pressure points, application of casting material, and molding the cast.

Begin by organizing the required supplies. Cast application requires the same material as that used in splinting (i.e., water, cotton cast padding, stockinette, and casting material). The width of the padding and casting material depends on the size of the extremity. The 4 to 6 inch wide rolls of casting material are generally used for lower extremity casts, whereas 3 or 4 inch wide rolls are generally used for the upper extremity. **Use the widest casting material available and possible in order to limit the number of turns of the fiberglass or plaster roll over joints and other curved surfaces.** Place all materials on a tray near the bedside including a bucket of tepid water. An assistant designated to dip and drain the casting material and help with patient positioning is immensely helpful.

Prepare the patient. Position the extremity and the patient appropriately for cast placement. The patient is frequently able to assist in the process. Cover the patient with gowns or towels to keep casting material off their clothes.

Apply tubular stockinette to the extremity (**Figures 113-3A and 113-3B**). The stockinette is not a necessary component of casting but many Emergency Physicians use it as a first layer.⁷ It provides a smooth covering over the skin that wraps neatly over both ends of the cast. Roll up the stockinette. Place it over the distal extremity as if you were putting on a sock (**Figure 113-3A**). Unroll the stockinette up the extremity (**Figure 113-3B**). Care must be taken to apply the stockinette gently. **Do not create tension in the stockinette by pulling it tightly. Eliminate any creases or redundancy of material by trimming any overlapping folds with a scissors.** For upper extremity injuries, cut a small hole one-third of the way from the end of one side of the stockinette to allow the thumb to pass through.

The primary layer of padding is provided by the cotton cast padding. **Casts and cast padding should be applied from distal to proximal.** Begin wrapping the cotton cast padding at a point that will be distal to the start of the plaster (**Figure 113-3C**). This initial band of padding is essential for protection against the cast edge. Keep the roll of padding in contact with the skin so that the material conforms easily to the contours of the extremity as it unrolls. Unroll the padding in a circumferential manner around the extremity. **The cotton cast padding must be laid down neatly and cleanly with no kinks or creases.** Each turn should overlap one-third to one-half of the previous turn. Tear off the extra cotton cast padding to eliminate excess material as you turn angles (e.g., ankle, heel, elbow, or thumb). **Lay the torn edges down by rubbing the padding smoothly.** Continue applying the padding, ensuring that it extends beyond the proximal end of where the cast edge will be to ensure skin protection at the cast edge. Excess length can easily be torn away after the cast is applied and hardened. Typically, two layers of cotton cast padding are adequate for protection between the skin and the casting material.

A

B

C

D

FIGURE 113-3. Preparing to place a cast. **A.** Apply an initial layer of tubular stockinette. **B.** The stockinette has been unrolled over the extremity. **C.** Begin and end the layering of the cotton cast padding at a site distal and proximal to where the casting material will end. Unroll the cotton cast padding in a circumferential manner, covering each preceding layer by one-third to one-half of its width. **D.** The cotton cast padding tears easily to provide additional layers of padding over bony prominences.

Pressure points occur over bony prominences or where excess padding has created an unnatural prominence. Palpate the obvious bony prominences to get a sense of whether or not there is adequate padding after the application of the two layers of padding. If the area feels vulnerable, place torn off pieces of cotton cast padding onto the exposed areas (**Figure 113-3D**). **Do not overpad bony prominences as excess layering can also lead to excess pressure.** Two to three layers of padding are adequate for most pressure points and bony prominences. Rub the torn edges of the padding so that they fuse smoothly to the underlying padding.

Place the rolls of casting material in a bucket of tepid water so that they are standing on end. Let the casting material remain submerged as long as air bubbles rise out from the center of the roll

(**Figures 113-2B and 113-2C**). Remove the rolls of casting material when all bubbles stop rising. Hold the casting material in both hands and squeeze some of the water out (**Figure 113-4**). **Do not wring the roll. Do not eliminate all the water from the roll.** Squeeze it gently. The remaining water in the roll is necessary for smoothing and molding the casting material into one solid unit. In general, casts should be applied with “wetter” material and splints with “drier” material as less time is required to apply a splint.

Apply the casting material (**Figure 113-5**). Place the roll of casting material on the extremity (**Figure 113-5A**). Unroll the casting material in a circumferential fashion around the extremity. **Never lift the roll of casting material off the extremity!** Continue each consecutive wrap around the extremity by overlapping the casting

FIGURE 113-4. Hold the casting material roll in both hands and gently twist each end to squeeze out the excess water. Keeping the free end of the casting material folded over will facilitate access after it has been removed from the water.

material by approximately 50%. The free border of the casting material will have excess material in it as the extremity changes in size. Grasp this excess casting material with the thumb and index finger of the nondominant hand (**Figure 113-5B**). Pull it outward

to create a tuck or a fold. Wrap this fold around the extremity (**Figure 113-5C**) and smooth the fold down against the extremity. This fold will barely be noticeable in the final product. As one roll of casting material ends, another should begin with a small amount of end-to-end overlap. Do not make consecutive folds at the same site as this will create bumps and add bulk to the cast.

Continuously mold and smooth the casting material with wet hands as each layer is applied. **This action ensures continuity of casting material throughout the cast and forms a smooth cast that conforms to the contours of the extremity.** Use only the palmar surface of the hands and proximal digits to mold and smooth the casting material (**Figure 113-5D**). Excessive use of the fingertips will produce irregular indentations and pressure points. Molding around irregular bony areas is best accomplished with two hands simultaneously rubbing the plaster. **Do not allow excessive time to pass between applying each layer of the casting material, as lamination between layers may not occur. This will weaken the cast considerably.**

A cast thickness of 1/4 inch is felt to be adequate. This usually requires four to five layers of plaster or three to four layers of fiberglass. Allow the cast to set and dry with no further manipulations by the Physician or the patient. The time for drying is variable depending on the casting material used, the water temperature, and the thickness of the cast. Typically, let the casting material set

A

C

D

FIGURE 113-5. Apply the casting material to form the cast. **A.** Lay the roll of casting material on the extremity and unroll it. **B.** As the limb changes in girth there will be excess plaster. Use the nondominant hand to pull on the excess material. **C.** Fold the excess material back onto the extremity in a neat tuck. Each tuck should be laid down smoothly with a molding of the hand. **D.** The casting material is laminated smooth with a continuous motion of the palmar surface of the hand and the proximal fingers.

FIGURE 113-6. Fold the free ends of the cotton cast padding and the stockinette over the edges of the casting material to finish the cast.

over a period of 10 to 15 minutes. Fold the free ends of the cotton cast padding and the stockinette over the edges of the cast as it sets (**Figure 113-6**). This prevents the rough edges of the casting material from irritating and abrading the skin. Secure the edges of the cotton cast padding neatly with tape or thin strips of casting material.

It is a common practice to bivalve the cast with a cast saw if the potential for increased swelling of the extremity is a concern (**Figure 113-7**). Cut completely through the length of the cast in two spots 180° apart (i.e., medial and lateral or anterior and posterior). This simple maneuver provides some room for edema without compromising the integrity of the reduction or the strength of the cast. **The underlying cast padding must also be split. Splitting the plaster alone will not reduce the pressure sufficiently.**

In the future, three-dimensional (3D) printing may affect how casts are made.^{15,16} Recently developed is the Cortex cast. It uses nylon to make a rigid and fishnet-like stocking after an extremity scan. It is thinner and lighter than the traditional cast. The Cortex has other advantages including the following: dressing with clothes over it is easier, it uses less material to make, no waste is produced when making the cast, it is fully ventilated, showering can be done without covering the cast, the underlying skin can be visualized, there is no padding to smell with time, and it can be recycled when taken off.

FIGURE 113-7. Splitting of the cast can be achieved with a cast saw that cuts through the thickness of the plaster. Cut the underlying protective material with a scissors.

UPPER EXTREMITY CASTS AND SPLINTS

COAPTATION SPLINT

A coaptation (“to bring together”) splint is used primarily in the acute setting for humeral shaft fractures that are nondisplaced or minimally displaced. This splinting technique allows for motion of the hand and wrist while limiting shoulder and elbow mobility. The cotton cast padding should extend from the nape of the neck to the axilla to avoid skin breakdown. The patient should then be placed in a sitting position to minimize splint displacement during the actual application process. The length of the splint extends from the axilla, around the 90° flexed elbow, along the outer arm, over the deltoid muscle, and over the acromion process (**Figure 113-8**). **It is critical that the splinting material extend over the deltoid muscle and the acromion process.** The shoulder portion can be held down by applying 3 inch wide tape over the portion of the splint that covers the acromion. Secure the splint with an elastic bandage that covers the entire splint. The major pitfall is making the splint too short and having it fall off! A splint that is too long will not provide proper immobilization. Always leave plenty of length over the shoulder. Padding is required to minimize axillary irritation. The disadvantages of this splint include the possibility of fracture displacement and extremity shortening. The splint should be replaced with a functional brace or cast after a short period of immobilization for pain control.⁴

FIGURE 113-8. The coaptation splint. The overwrap has been omitted for easier visualization of the splint.

FIGURE 113-9. The sugar tong splint. Leave the metacarpal joints free for flexion and extension. The overwrap has been omitted for easier visualization of the splint.

SUGAR TONG SPLINT

Sugar tong splints may be used for mid-forearm fractures, distal forearm fractures, and some wrist fractures. They are most commonly recommended for minimally displaced and distal ulnar and radial fractures (e.g., Colles and Smith). This splint immobilizes the elbow and wrist joints to prevent supination and pronation of the forearm (**Figure 113-9**). The splint begins at the palm, just proximal to the metacarpophalangeal (MCP) joints. It has the distinct advantage of allowing the MCPs to remain free, preventing stiffness in those joints.

Measure the required length of splinting material along the volar surface of the hand (starting just proximal to the MCP joints) and forearm, around the elbow, and back on the dorsal surface of the forearm ending just proximal to the MCP joints. **The MCP joints should be left completely free to prevent stiffness.** Early mobilization of the fingers will help to reduce swelling. Apply cotton cast padding from the MCP joints to just proximal to the elbow. The ulnar styloid process and the olecranon process are two bony prominences that need extra padding for comfort and prevention of pressure sores. The free ends of the splint also need added protection to minimize hand discomfort. Apply the splint. **Mold the splinting material with great caution to prevent closure of the sides of the splint thus forming a closed cast.** Fold and/or cut the volar and dorsal splinting material to ensure that the finger MCP joints are freely mobile (**Figure 113-9**). The splint can be modified to avoid potential skin breakdown at the posterior elbow.¹⁷

POSTERIOR LONG ARM SPLINT

Distal humeral fractures and proximal forearm fractures can be immobilized in a posterior long arm splint (**Figure 113-10**). It is also useful for fractures of the radial head and neck, olecranon fractures, and severe ligamentous injuries to the elbow. The posterior long arm splint extends from the axillary crease area, behind the elbow, distally to incorporate the wrist joint, and ending at the MCP shafts (**Figure 113-10**). This splint immobilizes the elbow in a range of 45° to 90° with the forearm in supination, pronation, or neutral positioning depending on the type of injury. The wrist can also be in a flexed, extended, or neutral position. **The metacarpals should not be immobilized in this splint unless the distal forearm or wrist fracture is comminuted.** Despite the many possibilities, the posterior long arm splint is usually applied with the elbow flexed 90°, the forearm neutral, and the wrist neutral (**Figure 113-10**).

FIGURE 113-10. The posterior long arm splint. The forearm and wrist are in a neutral position. The padding and overwrap have been omitted for easier visualization of the splint.

RADIAL GUTTER SPLINT

The radial gutter splint is used for the treatment of stable phalangeal and metacarpal fractures of the index or middle fingers. The splinting material extends from the pulp of the distal fingers to the proximal forearm (**Figure 113-11**). It is helpful to measure and cut a hole in the middle of the splinting material to allow for the insertion of the thumb prior to wetting the splinting material. Place cotton cast padding between the index and middle fingers prior to applying the splint to prevent skin maceration. Mold the width of the splinting material around the radial aspect of the index finger, middle finger, hand and forearm to create a stabilizing force. The ulnar aspect of the hand and forearm is left entirely free. The hand is immobilized in what is considered a “safe” position with the wrist dorsiflexed 20°, the MCP joints flexed 60° to 90°, and the interphalangeal (IP) joints extended or slightly flexed at 10° (**Figure 113-11**).¹⁸ This is also known as the “position of comfort.” It can be described as if the patient were holding a can of soda. The fingertips should be visible to allow for repeat neurovascular examinations.

ULNAR GUTTER SPLINT

This splint is used for the treatment of stable metacarpal and phalangeal fractures of the ring and small fingers (**Figure 113-12**). The long axis of the plaster extends from the pulp of the distal fingers to the proximal forearm. Place cotton cast padding between the

FIGURE 113-11. The radial gutter splint with the hand in the “safe” position.⁹

A

B

ring and little fingers to prevent any maceration (**Figure 113-12A**). The width of the plaster must wrap around the ulnar aspect of the hand and forearm. Mold the splint around the forearm, hand, fourth finger, and fifth finger. The radial side of the hand is left entirely free. The hand is immobilized in the “safe” position with the wrist dorsiflexed 20°, the MCP joints flexed 60° to 70°, and the IP joints extended or slightly flexed at 10° (**Figure 113-12B**).¹⁸ The fingertips should remain visible to allow for repeat neurovascular examinations.

VOLAR SPLINT

The volar splint can be used for the treatment of wrist fractures, radial styloid fractures, ulnar styloid fractures, metacarpal fractures, middle phalangeal fractures, and proximal phalangeal fractures. This splint remains only on the volar surface of the hand and forearm as the name suggests. The splint begins at the proximal forearm and ends just proximal to the MCP joints (**Figure 113-13**). The splint can be modified and extended to include the fingers for phalangeal fractures with the wrist dorsiflexed 20°, the MCP joints flexed 60° to 90°, and the IP joints extended or slightly flexed at 10°.

DORSAL (“CLAM DIGGER”) SPLINT

The dorsal splint can be used in place of a volar splint for injuries of the distal forearm, wrist, or hand. The splint runs along the dorsal surface of the forearm and hand, from the proximal forearm to the ends of the digits. As with the volar splint, the wrist is extended 15° to 20°, the MCP joints are flexed 60° to 90°, and the IP joints are extended or slightly flexed to a maximum of 10°.

The dorsal splint maintains better control of the MCP and IP joints, assuring that the hand remains in the “safe position” when compared to the volar splint. Pad the splint adequately to prevent pressure sores since the dorsal surface of the hand lacks the intrinsic fat pads of the palm.

THUMB SPICA SPLINT

Scaphoid fractures, navicular fractures, carpometacarpal subluxations and dislocations of the thumb, and collateral ligament injuries of the thumb can all be immobilized in a thumb spica splint (**Figure 113-14**).¹⁹ This splint extends to the proximal forearm. It can be extended proximally to include the elbow joint if required.

It is positioned on the forearm, like a radial gutter splint, but only the thumb is immobilized. There are several methods to forming a thumb spica splint. One can simply lay the plaster over the radial aspect of the forearm and thumb. It is useful to cut one side of the

FIGURE 113-13. The volar splint. The overwrap has been omitted for easier visualization of the splint.

A

B

C

FIGURE 113-14. The thumb spica splint. **A.** One technique of thumb spica application with the splinting material cut to conform to the thumb. **B.** Cutting the splinting material facilitates this different technique of thumb spica application. **C.** The final product with the wrist dorsiflexed 20° and the thumb positioned as if a glass were being held in the hand.

splint into a shape that conforms to the thumb to facilitate the placement of the splint material around the thumb (**Figure 113-14A**). Cutting a wedge out of one side of the plaster will allow for easier splinting of the thumb without excess material collecting in the

first web space (**Figure 113-14B**). Position the thumb as if a glass were being held in the hand with the wrist in 20° of dorsiflexion (**Figure 113-14C**).

FINGER SPLINTS

Immobilization of the finger lends itself to great creativity in the field of splinting.²⁰ Finger splints may be adequate for immobilization of stable finger fractures, reduced dislocated joints, or ligamentous strains. Splint the finger in full extension if it involves an extra-articular fracture of the distal phalanx. Splint the finger in slight flexion if it involves the strain of a joint or ligament. The finger can be splinted in isolation or it can be immobilized with the adjacent finger for additional stability. Applying a single-digit or two-digit splint allows neighboring joints to remain mobile. Splinting material is rarely used for finger splints in the modern hospital setting. The creation of foam-padded metal or plastic splints has facilitated immobilization of the affected digit. Nonetheless, small strips of cut splinting material can still be used to stabilize any finger injuries. **The juxtaposition of the affected finger with its neighboring finger requires padding between the digits to prevent skin maceration and breakdown.**

SHORT ARM CAST

The short arm cast is used for stable fractures of the metacarpals, the carpal bones, the distal radius, and the radial or ulnar styloid processes (**Figure 113-15**). The short arm cast begins at the proximal forearm and extends to include the palm and the dorsum of the hand. The metacarpophalangeal and elbow joints are left exposed to allow for full motion at these joints. Flex the patient's elbow 90° (**Figure 113-15A**). Place the wrist in the desired position. The extent of flexion and ulnar-radial deviation of the wrist is determined by the underlying injury. The forearm can be in a neutral, pronated, or supinated position. Apply bias stockinette (**Figure 113-15B**). Apply cotton cast padding (**Figure 113-15C**). Ensure that extra padding is applied to the bony prominences of the base of the thumb and the ulnar styloid.

Apply the casting material. Roll the casting material over the padding from the hand to the forearm. A quick trim of the casting material will allow for a better fit as it passes around the thumb (**Figure 113-15D**). **Provide adequate space for the thumb so that its motion is not limited.** The application of additional layers to the anteromedial surface will strengthen the cast (**Figure 113-15E**). Mold the cast with an anterior-posterior force applied to the forearm and not up and down strokes (**Figure 113-15F**). Use smooth, rapid, and repetitive motions to mold and laminate the casting material. Trim the casting material while it is still wet to even out the thumb opening and the cast ends (**Figure 113-15G**). Ensure that all protective padding is pulled out from under the casting material to protect the skin from the sharp edges of the splinting material (**Figure 113-15G**). The patient should be able to touch the tips of the thumb and index fingers when the cast is properly applied (**Figure 113-15H**).

LONG ARM CAST

A short arm cast can easily be extended into a long arm cast if needed. Simply extend the cast proximally with the elbow in 90° of flexion. Extend the padding and the casting material to the proximal humerus, ending two or three finger breadths distal to the axilla (**Figure 113-16**). Be careful to provide adequate padding around the axilla or the patient will complain about the sharp cast edge.

A

B

C

D

FIGURE 113-15. The short arm cast. **A.** Flex the elbow 90°. The patient can help position the wrist and fingers in a position of function. **B.** Tubular stockinette is applied to the entire arm in anticipation of a long arm cast. **C.** Cotton cast padding is applied to the forearm. Adequate padding is also needed at the thumb as it will remain exposed and mobile. **D.** Cut one side of the casting material as it is wrapped around the thumb. Less bunching of excess material occurs with quick cuts of the casting material. **E.** An additional length of casting material (four to five layers) can be applied along the ulnar length of the cast. This serves as reinforcement if additional strength is necessary. **F.** Mold the cast with the palmar aspect of the hands. **G.** The wet casting material and underlying padding are cut and folded back to fully expose the thumb. **H.** The “okay” sign of a properly exposed thumb.

LOWER EXTREMITY SPLINTS AND CASTS

SHORT LEG SPLINT (ANKLE SPLINT)

The short leg splint helps to immobilize isolated ankle injuries with the joint at a 90° angle (**Figure 113-17**). This splint is commonly used for ankle fractures and sprains. It can also be helpful for certain stable fractures of the foot. This splint can be applied as a posterior

splint or a lateral to medial stirrup splint.²¹ Combining the two techniques can provide additional support for the ankle and is known as a trilaminar splint. The first part (i.e., the posterior splint) provides posterior support to the foot and ankle. The second part creates a medial-to-lateral stirrup-like splint around the sides of the ankle for additional stability.

Place the patient prone, if there are no contraindications, with their knee flexed 90° and the foot pointing upward (**Figure 113-17A**). Apply the stockinette (**Figure 113-7A**) followed by cotton padding (**Figure 113-7B**). Place the posterior support of splint material from the proximal posterior calf, passing under the heel, and along the plantar surface of the foot (**Figure 113-17B**). It can be extended distal to the toes to provide protection. Place the foot 90° to the tibia and in neutral rotation.

For a “stirrup” support of the ankle, begin by applying splinting material to the length of the medial aspect of the proximal calf, over the medial malleolus, under the heel, and up the lateral aspect of the ankle and calf (**Figure 113-17C**). The stirrup portion should be long enough to go from mid-tibia to mid-tibia when wrapped under the affected foot. Fold and smooth the edges of the stirrup around the heel (**Figure 113-17D**). Keep the ankle flexed 90° with the foot neutral while the splint material sets (**Figure 113-17E**).

LONG LEG SPLINT

This splint is commonly used for knee and tibial injuries prior to and after surgical fixation. It is basically a longer extension of the short leg splint described above. Posterior, medial, and lateral

A

B

FIGURE 113-17. The short leg or ankle splint. **A.** Stockinette is applied, and the leg is positioned. **B.** The splinting material is applied posteriorly. **C.** A stirrup splint is applied around the medial to lateral ankle. **D.** Fold the corners and smooth out the splint. **E.** An elastic wrap is applied over the splint after folding back the stockinette. The foot is maintained in this position until the plaster sets.

C

D

E

FIGURE 113-17. (Continued)

lengths of splinting material are used to stabilize the leg while the anterior aspect of the leg is left exposed. Measure the extremity from the gluteal crease distally to the tips of the toes. It is important to add an additional 1 to 2 inches to the measured length so that the splinting material can be folded back on itself to protect the patient from the sharp ends. The application of medial and lateral splinting material begins at the upper thigh just below the level of the gluteal crease and travels down the knee, calf, and under the ankle. The posterior portion of splinting material begins at this same level and travels down the posterior aspect of the leg, behind the knee, curving around the heel, and ending just beyond the ends of the toes. Flex the foot 90° to the tibia, flex the knee 10° to 30°, and mold the cast. Failure to keep the ankle at 90° will allow the Achilles tendon to shorten and stiffen. A pillow may be placed under the knee to maintain 20° to 30° of flexion while the splint hardens.

SPLINT FOR ACHILLES TENDON RUPTURE

Rupture of the Achilles tendon can be managed surgically or conservatively with immobilization. Surgery is often delayed and the patient will require immobilization in the “equines” position. Position the patient as if placing a short leg splint or have the patient sit up with the affected extremity hanging over the table’s edge. Position the foot in 20° to 30° of plantarflexion (**Figure 113-18**). This is a position that the foot will naturally relax into. Place a posterior splint on the lower extremity extending from the proximal calf

FIGURE 113-18. Positioning and splinting of the patient with an Achilles tendon injury.

FIGURE 113-19. The short leg cast leaves the knee and tibial tuberosity exposed. The finger is pointing to the tibial tuberosity.

to the distal aspect of the toes. Cut out wedges of plaster in order to minimize buckling at the malleoli as the splint material wraps around the heel.

SHORT LEG CAST

The short leg cast is used for stable ankle fractures and stable fractures of the hindfoot, midfoot, and forefoot (**Figure 113-19**). Place the patient either supine or sitting on the edge of the gurney. Place a padded block under the distal thigh if the patient is supine. Instruct an assistant to hold the patient's toes to help keep the lower extremity in a good position. Holding the leg by the toes may allow the force of gravity to disrupt fracture alignment. Care must be taken to prevent this outcome. The patient can sit upright on the edge of the gurney with the affected leg hanging down freely if no assistant is available.

The short leg cast begins at the proximal calf, below the knee, and extends down to the toes (**Figure 113-19**). The knee and tibial tuberosity are left entirely free to allow for full flexion and extension. The toes can be left entirely exposed or the cast can provide a hard sole of support and protection beneath the toes. Apply cotton cast padding with extra attention to the areas of bony prominence such as the fibular head, the lateral malleolus, and the medial malleolus. Apply the casting material from the calf to the toes as if applying a short arm cast. Mold the casting material around the Achilles tendon, away from the malleoli, and to conform to the plantar arch. Cut the wet casting material under the metatarsal heads to expose the toes or leave it long to support the entire toes.

Converting a short leg non-weight-bearing cast to a walking cast requires small adjustments to the existing cast. Supplement the arched foot of the short leg cast with additional casting material to form a flat surface. **Apply a preformed heel after the cast has completely dried to prevent any indentation.** Place the walking heel in the midsagittal plane of the foot with the center aspect lining up with the anterior calf. Secure the heel in place with copious casting material wrapped around the foot and ankle (**Figure 113-20**).

LONG LEG CAST

The long leg cast can be used for immobilization of distal femoral fractures, proximal tibial fractures, or knee injuries (**Figure 113-21**). The cast extends from the metatarsal heads to several finger breadths below the groin. The leg is immobilized with the knee in slight flexion and the foot 90° to the tibia with no inward or external rotation (**Figure 113-21**). Extending the short leg cast up to the groin is a safe

FIGURE 113-20. Converting the short leg cast into a walking cast. A walking heel is secured with additional casting material overwrappings.

and stepwise technique of forming a long leg cast. Be sure to provide sufficient overlap of casting material at the junction between the two casts. Inadequate overlap will weaken the integrity of the cast. Support the knee in slight flexion while the casting material sets. Make sure that there is adequate padding around the proximal free edge of the cast to protect the patient's groin.

KNEE IMMOBILIZERS

Knee immobilizers can be made using splinting material and are indicated for ligamentous injuries. Measure the extremity starting 10 inches above the patella to 10 inches below the patella. Double that length and cut the splinting material. Fold the splinting material end to end. Make a cut in the folded side extending from one edge to the middle of the folded side to create a hinge. Apply cotton cast padding starting 10 inches above the patella to 10 inches below the patella. Place the hinged portion of the splinting material 10 inches below the anterior patella with the cut ends extending proximally up both the medial and lateral leg. Secure the splinting material with a loose fitting elastic bandage.

AFTERCARE

The most feared complication of a splint or cast application is the development of a compartment syndrome. The aftercare is geared toward edema reduction and patient education. Instruct the patient

FIGURE 113-21. The long leg cast.

regarding the early signs of a compartment syndrome. This includes increased pain, pain with passive motion, paresthesias, pallor, decreased or altered sensation, as well as delayed capillary refill. The patient should return to the Emergency Department immediately if they develop any of these symptoms, if the digits become cold or blue, or if the patient has other concerns. The extremity should be maintained above the level of the heart for the first 48 to 72 hours after the injury. Ice should be applied to the surface of the cast or splint for at least 15 minutes three times a day. The cold therapy will be transmitted through the cast or splint and result in significant reduction of edema. Active motion of the fingers and toes should be encouraged to help reduce edema in the extremity. **The cast or splint must be kept completely dry.** Should bathing be desired, instruct the patient to place two plastic bags over the extremity and tape the proximal edge to the skin of the extremity. Sufficient pain medication should be supplied to last the patient until their follow-up visit with an Orthopedic Surgeon. This should include nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics. A sling may facilitate mobilization for some upper extremity injuries.

COMPLICATIONS

The most common complications associated with the application of a cast or splint include plaster sores, compartment syndrome, joint stiffness, thermal injury, infection, and allergic reactions.^{4-6,10,14,22} There are also problems with the process of application as described throughout the chapter.²³ The following section focuses on the prevention of these complications.

PLASTER SORES

Plaster sores result from ischemic necrosis of the skin underneath a cast or splint. The skin begins to exhibit necrosis after only 2 hours of continuous pressure. **Great care should be taken in applying a cast or splint and only molding it with the broad surfaces of the hands. Molding with the fingers can result in indentations and localized areas of pressure. The cast or splint should never be allowed to rest on a hard or pointed surface until it is completely dry.** Points of contact on the hard surfaces may cause impressions that result in increased pressure. Extra padding over bony prominences may decrease the incidence of plaster sores.

Complaints of pain should be taken very seriously. The cast or splint should be split or removed immediately and the skin examined. If the pressure point is not addressed rapidly, the pain will often subside as the skin becomes necrotic. This oversight often results in a foul-smelling pressure sore under the cast or splint when the patient returns for follow-up. Cast and splint treatment may be rife with complications for patients with limited sensation from underlying medical conditions (i.e., diabetes, paraplegia, or a myelomeningocele). **Great care should be taken and extra padding used when casting or splinting these individuals.**

Common areas of pressure necrosis also include the proximal and distal ends of the cast or splint. These are areas of stress concentration. **Great care should be taken in padding the ends of the cast or splint during the application. No plaster or fiberglass should ever touch the skin directly. If the edges of the splint are sharp or too long, they should be folded out and away from the patient.**

COMPARTMENT SYNDROME

A compartment syndrome is a significant complication from the application of a cast or, less commonly, a splint. The rigid immobilization prevents soft tissue expansion from edema and decreases the amount of fluid needed to raise compartment pressures.²⁴

In cases of acute fractures, casts should be used with caution and always split in the direction perpendicular to the force needed to maintain the reduction. **For example, after casting a distal radius fracture where a dorsal mold is needed to maintain the reduction, split the cast longitudinally on the volar and dorsal surfaces (i.e., bivalved) to allow for mediolateral spread of the plaster. Splinting greatly reduces the chance of iatrogenic-induced compartment syndromes because, unlike casting, splints do not harden circumferentially.**

It is not sufficient to split only the plaster. The plaster and underlying cotton cast padding must be split to visualize the skin underneath. Making a single longitudinal cut (i.e., univalving) in the cast can also decrease the compartment pressure. Univalving the cast can decrease intracompartmental pressures by 30%.²⁵ Spreading the cast 1 cm after cutting it can lower the pressure 60%.²⁵ Splitting the cotton cast padding will decrease the pressure by 70%.²⁵

JOINT STIFFNESS

Joint stiffness is a significant complication of joint immobilization with casts and splints. Sometimes the immobilization is unavoidable, as with the incorporation of the ankle and the knee in a long leg cast. **Every effort should be made to decrease adjacent joint immobilization as soon as it is safe and practical.** An example would be converting a long leg cast into a short leg cast.

Immobilize the extremity in a position of function as long as this does not interfere with the maintenance of fracture reduction. For example, take great care not to immobilize the ankle in plantarflexion when applying a lower extremity splint or cast. This mistake is commonly seen when a long leg cast is placed. This pitfall may be avoided by the stepwise application of the cast. First apply the cast to the foot and ankle with the ankle held 90° to the tibia. Second, extend the cast proximally to become a short leg cast and mold the reduction. Finally, extend the cast up the thigh as needed. An additional benefit is the reduction of anterior compartment pressures of the leg when the foot is held in up to 37° of dorsiflexion.

Great care should also be taken in splinting the upper extremity. **Every effort should be made to leave the fingers mobile at the metacarpophalangeal joints.** Immobilization of the metacarpophalangeal joints in extension results in shortening of the collateral ligaments and limitation of flexion. **Immobilize the metacarpophalangeal joints in 90° of flexion if they must be immobilized.** This position keeps the collateral ligaments in a lengthened position and allows a rapid return to function.

THERMAL INJURY

Thermal injury may result from the exothermic reaction of plaster or fiberglass as it sets or dries. The heat generated during the setting increases as the number of layers (i.e., thickness) increases as well as the temperature of the water increases. Also important is the ability to dissipate the heat generated by the drying plaster or fiberglass. Placing a cast or splint on a plastic pillow as it dries will result in reflection of the heat and an increased temperature within the cast or splint.⁶ The use of cloth pillows or towels under the cast or splint allows for some dissipation of the heat. Optimal heat dissipation occurs by exposing the cast or splint to circulating air.

Sufficient cotton cast padding must be used to protect the skin. Plaster and fiberglass must never touch the skin directly. The incidence of thermal injury can be decreased by using cool water and as thin a layer of plaster or fiberglass as possible to accomplish stable immobilization of the extremity. Great care should be used in the application of a cast or splint to anesthetized patients, insensate limbs, or confused patients.

INFECTION

Infection secondary to a cast or splint is uncommon and is usually related to open wounds or exposed surgical pins underneath the plaster. Fresh water should be used to wet the plaster. Do not use standing or previously used water, as it is an excellent culture medium. All wounds should be dressed with sterile gauze and cotton cast padding prior to applying the cast or splint. Windows can be created over wound sites to allow for regular care and evaluation. Patients should be instructed to keep casts and splints clean and dry so as to prevent skin maceration.²⁶

ALLERGIC REACTIONS

Allergic reactions to cotton, fiberglass, and plaster have been reported but are exceedingly rare. Orthopedists and orthopedic technicians may develop a contact dermatitis from continued exposure to plaster over many years. Gloves should be worn for plaster and fiberglass application.

SUMMARY

The initial management of orthopedic trauma is a fundamental aspect of Emergency Medicine. Fractures and dislocations of the extremities are routinely handled in the Emergency Department with prompt Orthopedic follow-up or consultation. The application of external immobilization can be the definitive or temporizing management of the injured extremity. The application of splints accounts for the majority of immobilization of injured extremities. Cast application plays a role in maintaining bony alignment following closed reductions of fractures.

Clear benefits of external immobilization include pain relief and the reduction of further soft tissue injury from bony fragments. Immobilization of the fracture decreases motion and traction on the nerve-rich periosteum.^{4,11} The immobilization of fracture ends protects adjacent neurovascular structures from injury and helps prevent bony fragments from penetrating the skin. External immobilization also reduces the area available for hemorrhage and decreases bone bleeding.⁴ Early immobilization leading to fracture stabilization is also important in reducing the morbidity associated with long bone fractures.²⁵ Finally, the closed treatment of fractures facilitates the body's natural processes of repair. External periosteal and internal intramedullary callus formation is optimized in the setting of bony alignment that has been secured by casting or splinting.

The application of splints is an essential skill for any Emergency Physician. The application of a cast in the Emergency Department is appropriate in some select situations. The casting or splinting of an extremity is simple, easy to perform, and relatively quick.

Skin and Soft Tissue Procedures

114

General Principles of Wound Management

Ivette Motola and John Sullivan

INTRODUCTION

An acute wound can be defined as a traumatic disruption in the integrity of the skin, including the epidermis and dermis. **The goals of wound management are to restore tissue continuity and function, minimize chances of infection, repair with minimal cosmetic deformity, and distinguish wounds that require special care.** The principles of wound management will be emphasized over specific repair techniques in this chapter. The following chapters will discuss specific details regarding different wounds. **Appropriate management of a wound will result in optimal healing while minimizing the risk of complications.**^{1,2} This includes wound cleaning, debridement of the wound edges if needed, and

determination of whether a wound requires closure, when wounds are closed, and how wounds will be closed.³

PHYSIOLOGY OF WOUND HEALING

THE THREE PHASES OF WOUND HEALING

There are three phases of wound healing (**Figure 114-1**). The first phase involves coagulation and inflammation. The second phase is the proliferative phase. The final phase is the re-epithelialization or remodeling phase.

Phase I consists of coagulation and inflammation, also known as the vascular phase. It occurs in the first 5 days. A fibrin clot forms a transitional matrix that allows for the migration of cells into the wound site over a period of 72 hours. Elevated levels of immunoglobulin G and wound C-reactive protein are found in this phase of wound healing. Inflammatory cells (i.e., macrophages, monocytes, and neutrophils) break down soluble wound debris, kill microbes, prevent microbial colonization, and secrete cytokines.⁴

FIGURE 114-1. Wound healing. (Photo courtesy of www.shieldhealthcare.com.)

The cytokines signal fibroblasts to initiate phase II. Most sutured wounds develop an epithelial covering that is impermeable to water within 24 to 48 hours.

Phase II is the proliferative phase and occurs 5 to 14 days after the injury. Fibroblasts proliferate and synthesize a new connective tissue matrix that replaces the transitional fibrin matrix. Granulation tissue consists of abundant capillaries, epidermal cells that have migrated, fibroblasts, and immature connective tissue within the wound. Fibroblasts release collagen, a protein component of connective tissue. **The tensile strength of the wound at 5 days is 5% that of normal skin. Collagen formation peaks at day 7.**

Phase III is the remodeling, re-epithelialization, or maturation phase. It occurs from day 14 and lasts until there is complete healing of the wound. The new granulation tissue is being converted into a scar. The scar consists of a matrix with lower cell density and lower vascular density compared to unscarred skin, with increased thickness of collagen fiber bundles packed in parallel arrays.⁵ **The wound will have 15% to 20% of its full strength at 3 weeks and 60% of its full strength at 4 months.** Tensile strength continues to increase up to 1 year after wounding. The skin will eventually regain only 70% to 90% of its original tensile strength.

SCAR FORMATION

Approximately 6 to 12 months are required to form a mature scar. **This explains why scars should not be revised until 12 months have passed.**⁶ A wider scar, inadequate wound closure, or a wound dehiscence may occur in areas with increased skin tension or if the wound is in an area of excessive motion (e.g., over joints). Adequate immobilization of the approximated wound but not necessarily the entire anatomic part is mandatory after wound closure for efficient healing and minimal scar formation. **Contractures can develop when a scar crosses perpendicular to a joint crease. These patients may require physical therapy to prevent the loss of range of motion secondary to contractures.**

Hypertrophic scars result from full-thickness injuries. **Hypertrophic scars are characterized by a thick and raised scar that remains within the boundaries of the original injury (Figure 114-2A).** They must often be corrected by surgical intervention.⁵

Keloids are hypertrophic scars (i.e., thick and raised) that exceed the boundaries of the initial injury (Figure 114-2B). They can develop from superficial injuries and appear to have a genetic basis. Surgical intervention rarely resolves keloids. They may be prevented or minimized by application of pressure dressings, calcium channel blocker injections, glucocorticoid injections, and silastic dressings.⁵

The repair procedure may result in more scar tissue. Absorbable suture materials contribute to the formation of suture marks because of their increased reactivity whereas nonabsorbable materials do not. Wounds that are approximated too tightly can result in tissue ischemia and more scar tissue formation.

FACTORS ADVERSELY AFFECTING NORMAL REPAIR

It may be useful to divide factors that may negatively impact on optimal wound healing into local and systemic issues. Local causes of improper wound healing include tension on the wound edges and necrosis and/or ischemia of the tissues from local conditions. Crush injuries and contusions decrease blood flow and lymphatic drainage, which alters local defense mechanisms. Retained foreign bodies or contaminated wounds may result in wound infection and poor healing.

Wound infections occur as a result of the patient's resident flora and the environment. Infection is related to wound age, the

A

B

FIGURE 114-2. Abnormal scar formation. **A.** Hypertrophic scar. **B.** Keloid scar. (Photos used from www.commonswikimedia.org.)

amount of devitalized tissue, and the tissue concentration of pyogenic bacteria. A wound infection exists when there are bacterial densities of more than 10,000 organisms per gram of tissue.⁷ Bacteria slow wound healing by secreting proteases that directly injure the tissue in the wound.⁸ Bacteria secrete factors that lead to excess inflammatory cells in the wound which also causes injury to the tissue.⁹

Systemic factors are equally important to recognize when treating an acute wound. Hypovolemia is a major deterrent to wound healing in patients and may occur due to any form of shock. Sepsis originating from the wound or from systemic infection unrelated to the wound may result in a later cause of shock. Other systemic conditions that may result in impaired wound healing include atherosclerosis (i.e., causing peripheral arterial disease resulting in

decreased oxygen and nutrient delivery to the wound), collagen vascular disease, immunosuppression, microangiopathy secondary to diabetes, and renal insufficiency. Polymorphonuclear leukocyte function is known to be impaired from cancer, chronic infections, hyperglycemia, jaundice, and uremia.

Medications and nutrition can contribute to good wound healing or affect it adversely. A lack of protein, a lack of vitamins (e.g., vitamins A and C), and malnutrition may inhibit or prolong healing. Zinc deficiency is reversible and may play a role in retarding the healing process.⁹ Cytotoxic drugs can delay wound healing. Anti-inflammatory drugs (e.g., aspirin, colchicine, and glucocorticoids) disrupt collagen synthesis, macrophage function, and polymorphonuclear neutrophil concentrations. Glucocorticoids result in delayed wound repair by slowing cell proliferation.¹⁰

PATIENT EVALUATION AND ASSESSMENT

HISTORY

A thorough and accurate history and physical examination are essential for optimal wound management. Documentation of the patient's age, allergies (e.g., latex or local anesthetics), medications, prior tetanus immunization history, systemic illnesses, and the circumstances of the injury is essential to wound management. These principles are emphasized because the presence of disease processes (e.g., alcoholism, chronic malnutrition, diabetes mellitus, extremes of age, hepatic insufficiency, immune suppression, malignancies, and renal insufficiency) may impair host defenses or complicate wound healing.^{11,12}

The wound is often less important than an associated injury to an adjacent structure or cavity. Associated injuries can easily be missed without a specific directed search for their presence. There may be times where wound management is not the immediate concern. Initial trauma management always starts with assessing the patient's airway, breathing, circulation, and any life-threatening conditions. This must take precedence to definitive wound repair. There are times when a laceration may not be closed in the Emergency Department (e.g., a complex facial laceration in the setting of a traumatic intracranial hemorrhage presenting to a community hospital may require immediate transfer to a trauma center). Ask why the trauma occurred. The cause of the wound is straightforward in many instances. Abuse, metabolic abnormalities, or systematic abnormalities may have occurred. Abuse is especially important in elderly and pediatric populations.

Obtain a thorough history concerning the patient's tetanus immunization status. Important factors to consider in assessing the risk of developing tetanus include prior immunization history, the type of wound, the degree of wound contamination, the time from injury to treatment, and the presence of underlying medical disease.

MECHANISM OF INJURY

Severity of injury and associated injuries may be anticipated by determining the precise injury mechanism. This will often suggest whether there is additional soft tissue damage, the presence of a foreign body, or the amount of contamination present.

Document specific components such as how the injury occurred, when the injury occurred, where the injury occurred, and what contaminants were present or involved. Determine the position of the hand at the time of the injury, what kind of work the patient does, and which is the patient's dominant hand if the wound involves the hand. Complicated wounds (e.g., caused by animal or human bites, chemical exposure, or high-pressure injection) may require

a more extensive evaluation and consultation with the appropriate specialist.

The mechanism of injury may alter the disposition of a patient. A large but hemodynamically stable machete laceration on the back may be repaired in a community Emergency Department. A 2 mm puncture wound of the hand caused by a high-pressure paint gun may require transfer of care to a Hand Surgeon or to a trauma center depending on the local resources.

TIME OF INJURY

Time of injury must be determined as part of the history. The literature varies regarding if and when to close wounds when presentation to the Emergency Department is delayed. This can often be a challenging decision for the Emergency Physician. Wounds older than 10 hours, or 8 hours for the hand, were found to be at higher risk for infection.¹³ Another study performed in an underdeveloped country indicated that wounds might be approximated up to 18 hours after injury.¹⁴ Lacerations that are at low risk of infection (e.g., face, scalp, and torso with minimal contamination) may be closed primarily up to 12 to 24 hours after injury because of the excellent circulation in these areas.¹² Other lacerations may be closed primarily if they are less than 6 to 12 hours old if not heavily contaminated or located in high-risk areas (e.g., foot or hand). One important study concluded that diabetes, lower extremity wounds, wound contamination, and wound length greater than 5 cm were significantly more important than a defined cutoff point for wound closure in terms of risk of infection.¹⁵

CLASSIFICATION OF WOUNDS

Wounds are described and classified based on their cause and the type of injury (**Figure 114-3**). Abrasions are the result of grinding or abrading forces on the skin. The epidermis and/or dermis is disrupted but not removed in its entirety. Crush injuries are due to compressive forces. The patient sustains a large amount of kinetic energy that results in devitalized tissue, edema, and microvascular disruption. Crush wounds are 100-fold more likely to become infected than lacerations because of the much lower bacterial loads required for infection.¹⁰

Lacerations are wounds that are caused by shear forces that result in a tearing of the tissue. They are subclassified as avulsion, shear, or tension lacerations. Avulsion lacerations are injuries where there is sharp trauma at an angle that removes the epidermal and possibly the dermal layer of skin. The injury creates a skin flap. Shear lacerations are produced by a sharp force perpendicular to the skin surface that results in a tidy or clean wound. These wounds are usually caused by glass, knives, or sharp metal objects. There is little tissue damage and this type of wound is not prone to infection. Tension or tensile lacerations are injuries with jagged or contused edges that are created by a compressive force. These wounds pose a greater risk for infection than shear lacerations.¹⁶

Punctures result in a wound that is deeper than it is wide. The skin opening is small and the depth of the wound is often unknown. Puncture wounds are made by discrete and thin objects. **Puncture wounds carry a high risk for infection. Irrigation is mandatory for puncture wounds. The irrigation pressure must not be so high as to drive contaminants deeper into the wound.**

The wound may be clinically classified based on an estimate of microbial contamination and the subsequent risk of infection. Clean wounds are those that occur under aseptic technique. These are usually surgical incisions that are elective and preceded by a thorough skin cleansing and decontamination process. Clean-contaminated wounds are those associated with the usual and normal flora of the region. There is no contamination from foreign

FIGURE 114-3. Some of the common types of wounds. (Photo used with permission under license of shutterstock.com.)

bodies or pus. Contaminated wounds are those that are traumatic (e.g., lacerations and open fractures), less than 12 hours old, or associated with a break in aseptic technique. Most wounds seen in the Emergency Department are classified as contaminated. They may be associated with the introduction of “dirt” or foreign bodies into the wound. Dirty wounds are those that are heavily contaminated (e.g., feces or soil), occur through infected tissue, are over 12 hours old, are associated with retained foreign bodies, or are associated with devitalized tissue.¹⁷

WOUND ASSESSMENT

A complete examination and documentation of the laceration is necessary. This includes noting the location and depth of the laceration, the presence of any gross contamination, the presence of an obvious foreign body, and any associated injuries. **Measure the wound length and do not estimate the length visually.**¹⁸ Physicians are often wrong in their estimates of wound length. The length affects good documentation and billing.

Assessment of soft tissue wounds involves an examination of the surrounding neurologic structures, surrounding vascular structures, and tendons. Look for bony injuries and foreign bodies. Emergency Physicians must possess a working knowledge of functional anatomy, particularly the distal upper extremity and face.

HEMOSTASIS

Hemostasis must be achieved to adequately visually inspect a wound (Chapter 137). Hemostasis for most simple lacerations can be achieved with direct pressure. Determine the reason when several minutes of direct pressure do not achieve hemostasis. Is there an arterial injury? Is there a foreign body? Does the patient have a coagulopathy, either intrinsic due to hemophilia or medically induced? Use a blood pressure cuff or pneumatic tourniquet proximal to extremity wounds and inflated after raising the extremity to reduce venous blood to allow visualization of the wound and

elucidation of the cause of bleeding. Deflate any type of tourniquet after no more than 20 to 30 minutes to restore circulation and to determine if hemostasis has been achieved. Suturing the wound best controls bleeding of the scalp. There are several tourniquets available and hemostatic agents can be applied for more severe bleeding (Chapter 137).¹⁹⁻²¹ **Do not clamp vascular structures except small arterioles, small venules, and vessels within muscles. Vascular structures may require special techniques for hemostasis.**

FUNCTIONAL EXAMINATION

It is important to explore the deep structures through a full range of motion to detect partial tendon lacerations or joint capsule disruption. **Tendons can be evaluated by inspection. Test individual muscles for full range of motion and full strength.**

NEUROVASCULAR EXAMINATION

Perform a distal neurologic and vascular examination on extremity injuries. Check capillary refill distally. It should take less than 2 seconds. Neurologic assessment involves checking distal muscle strength and sensation. **Check two-point discrimination prior to the administration of anesthesia for hand and finger lacerations.** Two-point discrimination at 5 mm on the radial and ulnar aspects of the finger pads is the most efficient method of assessing median and ulnar nerve function. Two-point discrimination should be less than 1 cm at the fingertips. A crush injury may be associated with decreased two-point discrimination and may take several months for recovery. Numbness may be an early sign of a developing compartment syndrome (Chapters 93 and 94). Nerve lacerations may or may not be repaired depending on location and functional status of the patient. **Document any nerve lacerations and explain them to the patient and/or family.** A finger laceration resulting in distal sensory loss may be irrelevant in an elderly patient with severe dementia. The same injury may be extremely relevant for a professional pianist and may require referral to a Hand Surgeon.

EVALUATION FOR FOREIGN BODIES

Failure to identify foreign bodies in wounds may lead to complications (e.g., delayed wound healing, increased risk of infection, and loss of function).^{12,22} Foreign bodies and foreign matter greatly enhance the infectivity of a given bacterial inoculum.²³ Retained foreign bodies are a common complication of simple wound repair. **Perform a thorough inspection to attempt to diagnose the presence of a foreign body.** Missed foreign bodies have been noted in the literature to be one of the leading causes of lawsuits brought against Emergency Physicians. Many lawsuits brought against Emergency Physicians and up to a quarter of closed claims are related to retained foreign bodies.^{22,24,25} Some foreign bodies cause an inflammatory reaction (e.g., cloth, rubber from shoes or foam insoles, splinters, teeth, thorns, and wood), while others do not (e.g., glass, metal, most plastics, and pencil graphite).

Wound exploration, irrigation, and radiography or ultrasound may be needed when the clinical setting suggests a possible foreign body (Chapters 120 and 121). **Spread the tissue during exploration. Do not cut tissue and risk neurovascular injury. Puncture wounds have not been proven to benefit by coring or probing to determine the depth of the wound. Imaging may be required to detect retained foreign bodies.** Retained wood, thorns, and plastic are often detectable by wound exploration and ultrasound but may not be visible on plain radiographs. Radiographs will identify retained metallic fragments and more than 90% of glass foreign bodies if the glass does not have a low lead content and the fragments are at least 2 mm long.^{26,27} Other studies have shown that the lead content of glass does not actually contribute to visualization on plain radiographs.^{28,29} Wound markers can be used during radiography. Radiographs obtained in two planes can help localize the object for recovery. Glass may penetrate at an angle and be buried deeper than it appears. **The use of additional imaging (e.g., computed tomography [CT], magnetic resonance imaging [MRI], or ultrasound) may contribute to identification of foreign bodies when the clinical suspicion is high but suspected foreign bodies are not seen on radiographs or by direct visualization.**^{30,31}

Foreign bodies that do not cause an inflammatory reaction are not always removed from lacerations. This is especially true if there are multiple fragments or if excessive tissue disruption will result with attempted removal. **Make the patient aware of any retained foreign bodies at the time of discharge, their benign presence, why removal was not attempted, the possibility of later infection, and the fact that they may eventually self-extrude. This must also be documented in the medical record.** Wounds in a complex area (e.g., the palm) may require specialist consultation for immediate or delayed removal. The wound can be approximated loosely and immobilized for comfort and to avoid further tissue disruption. Prescribe antibiotics and arrange for appropriate outpatient follow-up in 24 to 48 hours.

EVALUATION FOR GROSS CONTAMINATION

Soils have varied levels of contamination potential. Sandy soils present a low risk of wound contamination. Clay-containing soils are pyogenic because they impair host defense mechanisms and promote inflammation. Organic soils contain *Clostridium tetani* and many concentrated bacteria. Soil contaminants can be removed by copious high-pressure irrigation. Leave contaminated wounds open and allow them to heal by secondary or tertiary intention.

Obtain radiographs if there is concern for an underlying fracture or possible bone exposure. Bone injuries require checking the overlying skin to exclude an open fracture. An open fracture is an indication for surgical debridement and operative repair. An exception is the distal phalanx fracture. These can be treated

with copious irrigation, oral antibiotics, and detailed discharge instructions.

HIGH-RISK WOUNDS

Many wounds require special consideration in deciding upon the method of closure, the type of suture to use, and the use of antibiotic prophylaxis. These include wounds contaminated by feces, organic material, saliva, soil, and vaginal secretions. **Immunocompromised patients or patients taking immunosuppressive drugs may require antibiotics and longer times for the stitches to remain before removal.** Bite wounds, foot wounds, and hand wounds require special care. Wounds greater than 6 to 12 hours old, other than wounds on the face, may require delayed closure. Puncture wounds may require radiographs, incision, exploration, and antibiotic prophylaxis. Wounds accompanied by excessive tissue damage and devitalization or crush injuries are prone to infection. Wounds with retained foreign bodies may require radiographs, exploration, and removal. Major tissue defects may be closed with advanced wound closure techniques (Chapter 118). Wounds overlying sites of active infection require antibiotics and delayed closure. These topics are covered later in this chapter and in other chapters of this book.

WOUND CLOSURE

OVERVIEW

Most patients presenting to the Emergency Department arrive with the expectation that their wounds will be closed. It is critical that the Emergency Physician understands the various options for wound closure including the decision to delay closure when patients are at high risk of infection. Patient education and specific follow-up are important as always. **Education and follow-up are crucial when patient expectations are not met for medically indicated reasons.** Below are definitions of the three wound closure techniques and information regarding when these techniques may best be used.

PRIMARY INTENTION

Primary intention involves surgically approximating the wound edges shortly after the time of injury. The skin's greatest strength is in the dermal layer. The best repair results when the entire depth of the dermis is accurately approximated to the entire depth of the opposite dermis. **Accurate approximation of the epidermis gives a cosmetically appealing effect to the repair but does not contribute to its strength. Wound eversion and the use of buried stitches can greatly improve healing by primary intention.**

SECONDARY INTENTION

Secondary intention involves allowing the wound to heal without any surgical intervention. The wound is left open and allowed to heal from the inner layer to the outer surface. It is a more prolonged healing process than primary intention. Excessive trauma, imprecise approximation of tissue, infection, or tissue loss may result due to healing by secondary intention. Wound contraction by granulation tissue containing myofibroblasts is the major influence on this type of healing. Wound contraction becomes more significant when the dermis is lost.

Concave skin wounds heal with the best results. These areas may heal better by secondary intention than by primary intention in well-cleaned wounds. This is simply because the skin naturally approximates in these regions (e.g., concave areas of the pinna,

inner ear, nasal alar crease, nasolabial fold, and temple). Flat surfaces (e.g., periorbital areas, side of the nose, and forehead) can heal well by secondary intention, although surgical intervention may be best. Wounds on convex surfaces (e.g., malar cheek, the tip of the nose, and the vermilion border of the lip) are not optimal for healing by secondary intention.⁸

TERTIARY INTENTION (DELAYED PRIMARY CLOSURE)

Tertiary intention or delayed primary closure can often decrease infection rates. Wound closure by tertiary intention is accomplished 3 to 5 days following the initial injury. **It is a combination of allowing the wound to heal secondarily for 3 to 5 days and then primarily closing the wound.** It is the safest method of repair for wounds that are associated with extensive tissue loss, contaminated, dirty, infected, at high risk of infection, and wounds “too old” to close. **The ultimate cosmetic result is the same as that of primary wound closure.** This method may not be ideal for young children having to return a second time for an uncomfortable procedure. This must be clinically weighed against the risk of infection which might result in the need for antibiotics, dehiscence, hospitalization, poor outcomes, or repeated visits. The site of the planned return visit may be the Emergency Department, specialist office (e.g., Plastic Surgeon), or wound care center depending upon the local resources and customs.

Delayed primary closure wounds are all at high risk of infection. This technique involves a thorough cleaning of the wound just as would be done with primary closure. Anesthetize the wound and irrigate it using high pressure. Consider scrubbing this type of wound with saline-moistened gauze, packing it with wet gauze, and then covering it with a surgical dressing. Instruct the patient to apply wet-to-dry dressing changes once or twice a day. Assess the wound for any signs of infection upon the patient's return. Anesthetize and clean the wound again. Scrub the wound base and edges with saline-moistened gauze and irrigate the wound to remove any dirt, debris, and granulation tissue. Stitch the wound to approximate and evert the wound edges. The postprocedural wound care is the same as if the wound was closed primarily.

SKIN AND WOUND PREPARATION

ANESTHESIA

Wounds are anesthetized with local or regional techniques prior to cleansing and repair. Local anesthesia may distort wound edges. Use regional nerve blocks (Chapters 155 to 158) where appropriate (e.g., ear, face, hand, nasal cartilage, palm, and sole). Refer to Chapters 153 through 159 for a complete discussion of local anesthetic agents, nitrous oxide anesthesia, procedural sedation, regional anesthesia, and topical anesthesia.

Lidocaine (Xylocaine) in a dose not to exceed 4.5 mg/kg is an effective and standard local anesthetic agent. Lidocaine anesthesia lasts approximately 60 to 90 minutes. Use bupivacaine if a longer period of anesthesia is required. Bupivacaine provides approximately 120 to 180 minutes of anesthesia. The addition of a 1:100,000 dilution of epinephrine to either will prolong the duration of anesthesia, promote hemostasis, and reduce systemic absorption of locally infiltrated anesthetic solution. Epinephrine is a potent vasoconstrictor and should not be used near end organs (e.g., fingers or toes). It may decrease blood flow and induce ischemia. Avoid epinephrine near the ear, penis, and tip of the nose.

The injection of local anesthetic is often painful. This pain can be reduced by using several techniques. The use of a 27 or 30 gauge

needle, addition of bicarbonate to lidocaine (i.e., 9 mL lidocaine to 1 mL of bicarbonate), slower and deeper infiltration into the dermis, and warming the local anesthetic solution may decrease the pain of anesthetic injection.³²⁻³⁷ Other strategies involve anesthetizing as much tissue as possible through a single site and starting proximally on the extremity and moving distally. Infiltration of the local anesthetic solution through the open wound edges is less painful than through intact skin.

Many reported “allergic” reactions to anesthetics are vasovagal or other adverse responses. True allergies to local anesthetics are rare and are generally seen only with the ester class of local anesthetics. The use of an ester class of local anesthetic is suggested if an allergy to lidocaine (an amide class of local anesthetic) is suspected. An alternative is the use of cardiac lidocaine. The prefilled syringes used in cardiac arrests and codes contain no preservative. It is felt that the preservative in lidocaine is responsible for the most allergic effects. Another alternative is to use a 1% to 2% solution of diphenhydramine (i.e., Benadryl). This provides adequate but not ideal anesthesia. The most common complication of local anesthesia infiltration is hypotension and bradycardia from a vasovagal reaction.

Topical anesthesia is an attractive alternative to injection, particularly in the management of pediatric patients with simple wounds. Lidocaine, epinephrine, and tetracaine (LET) or tetracaine, adrenaline, and cocaine (TAC) are two agents that can be used to provide effective local anesthesia.³⁸ **These agents contain epinephrine and should not be used on areas involving an end artery or contaminated wounds.** TAC involves expense and incorporates problems with the use and maintenance of a controlled substance. TAC also has the potential for toxicity, especially when applied to mucosal surfaces. EMLA (i.e., eutectic mixture of local anesthetics) cream has been found to provide effective anesthesia for extremity lacerations. EMLA is a combination of 2.5% lidocaine and 2.5% prilocaine suspended in an oil-in-water emulsion. It takes longer to obtain optimal anesthesia with EMLA than with TAC.³⁹

SKIN AND WOUND CLEANSING

Meticulous preparation of the skin surrounding the wound, thorough wound irrigation, and wound debridement when needed are critical to good wound healing. The goal of wound cleansing is to remove bacteria, foreign matter, and tissue debris. Anesthetize wounds prior to cleansing and/or local exploration. Use adequate light, anesthesia, and equipment to avoid inadequate debridement, a retained foreign body, or a wound hematoma that can result in a necrotizing soft tissue infection.

Disinfecting the intact skin surrounding the wound and ridding it of foreign bodies, debris, and particulate matter is the initial step in wound preparation. This technique can be accomplished by scrubbing the skin with povidone iodine, chlorhexidine, or poloxamer 188 (Shur-Clens) skin-prep solutions. **Do not expose the wound itself to these solutions.** Povidone iodine and chlorhexidine solution are bactericidal and work as they dry. Their toxicity to wound tissue is controversial. Shur-Clens has no tissue toxicity but also has no antibacterial activity. Prep a wide area surrounding the wound with an antimicrobial agent, preferably povidone iodine or chlorhexidine solution.

HAIR REMOVAL

Hair removal is often unnecessary prior to closing wounds, can be embarrassing for the patient after discharge from the Emergency Department, and may increase the risk of wound infection. Shaving can cause minimal soft tissue trauma and wound infections.⁴⁰ **Eyebrows can be shaved if necessary.** It is a myth that they do not

grow back.⁴¹ One meta-analysis of surgical preoperative patients showed that hair removal of any form did not decrease the risk of infection.⁴² Simple scalp lacerations can be exposed by using antibiotic ointment or lubricating gel to move the hair away from the wound margins prior to placing sutures or staples. This works in other hair-bearing areas of the body.

WOUND IRRIGATION

Wound cleansing and preparation have been proven to be the foundations of proper wound management and the prevention of wound infections. Irrigation removes contaminants, reduces infection, and improves visualization. There are concerns regarding wound irrigation. What is the pressure required for adequate cleansing of the wound? What means are available to irrigate the wound safely while protecting the health care worker from the threat of human immunodeficiency virus and hepatitis B by contamination?

Irrigation pressures of 5 to 8 pounds per square inch (psi) are felt to be adequate to cleanse a wound that is not heavily contaminated. This surface pressure can be generated by the combination of a 35 mL syringe and a 19-gauge angiocatheter held 2 cm from the wound surface.⁴³⁻⁴⁵ Take care as this process can be quite messy (**Figure 114-4A**). Use one of the many wound shields to decrease potential exposure and messes (**Figure 114-4B**). High-pressure irrigation generates peak pressures of 25 to 40 psi and has been a controversial technique in the Emergency Medicine literature. The theory is that high pressures may cause tissue disruption and increase infection rates. Reserve high-pressure irrigation for highly contaminated wounds. High-pressure irrigation may drive contaminants deeper into puncture wounds and should be avoided.

There are a variety of irrigation fluids and the optimal type is unknown. Normal saline is the most commonly used irrigant. Several studies have shown that tap water is as effective with no increased incidence of infection, especially when a large volume of irrigant is required.⁴⁶⁻⁵⁴ The volume of irrigation fluid to be used has not been well established. The use of 100 to 300 mL has been suggested in the literature. Heavily contaminated wounds require larger amounts of irrigant. Anecdotal recommendations suggest using 50 mL/cm for clean wounds and 100 mL/cm for dirty wounds. Heavily contaminated wounds may have to be scrubbed after adequate anesthesia with fine-mesh gauze or a micropore sponge using a 1% solution of povidone iodine or poloxamer 188. Soaking of wounds is discouraged and is a poor substitute for the preparation of contaminated or clean wounds. **Do not soak wounds in any fluid.** Soaking does not reduce bacterial contamination or decrease infection rates. Soaking may increase infection rates. **Do not use detergents, hydrogen peroxide, or undiluted povidone iodine in the wound as they cause tissue toxicity.**⁵⁵

Numerous commercially available devices are available to irrigate a wound. Use barrier protection to shield the eyes, face, mucosal surfaces, and skin during irrigation. There are several barrier devices on the market that decrease the splatter of irrigation fluid. Some of these devices are preattached to a wound irrigation device. Others can be attached to a wound irrigation device (**Figure 114-4C**).

WOUND DEBRIDEMENT

Debridement of wounds helps create straight and clean wound edges that are easier to repair by removing tissue that is contaminated by bacteria, contaminated by foreign matter, or devitalized and may impair the ability of the tissue to resist infection. Successful wound closure may require the transformation of a ragged

FIGURE 114-5. Wound debridement. Removal of the wound edges with a scissors (or a scalpel).

laceration, the removal of devitalized tissue, or the removal of contaminated tissue to convert a traumatic wound into a surgical wound (Figure 114-5). Devitalized and necrotic tissue must be removed to remove a nidus for bacterial growth and wound infection.^{12,56-58}

Close approximation of the wound requires that debridement of jagged edges not be too vigorous to avoid widening the wound and making it difficult to close. Wounds of the face or areas that are devoid of redundant tissue (e.g., feet or hands) require conservative debridement. Debridement to simplify wound closure is not always the answer for a superior cosmetic result in the repair of irregular wound edges. The meticulous repair of complex wound edges can often provide a superior cosmetic result than debridement.

Debridement can be accomplished mechanically, hydrodynamically, or with a combination of both methods. Tissue can be removed mechanically with a #11 or #15 scalpel blade or a scissors (Figure 114-5). Superficial debris and contaminants can usually be removed with high-pressure irrigation. **Debridement must be performed using aseptic technique. Scrubbing is not a substitute for debridement of heavily contaminated tissue. Handle wound edges delicately to avoid further soft tissue damage and devitalization of injured tissue.**

WOUND EXCISION

The entire wound may be excised in areas of excess tissue or tissue laxity if no blood vessels, joints, nerves, or tendons lie within or at the base of the wound (Chapter 118 and Figure 114-6). The excision of a wound creates smooth, clean edges that may be approximated with suture. This is especially useful in wounds that are heavily contaminated. Most wounds are excised using an elliptical incision (Figure 114-6). Other types of wound excision are discussed in Chapter 118.

Carefully plan the excision before removing any tissue. Mark the edges of the proposed incision with a sterile skin marking pen. **Make the long axis of the ellipse two-and-a-half to four times as long as the greatest width of the ellipse.** Removal of too much tissue will produce a large defect that may not be possible to primarily close. **Remove the tissue using aseptic technique to prevent any contamination of the new wound edges.**

FIGURE 114-6. Wound excision. Removal of an ellipse of tissue that contains the wound results in smooth, clean edges that can be approximated.

WOUND UNDERMINING

The undermining of tissue creates a “flap” that involves the separation of the skin and superficial subcutaneous tissue from the deeper subcutaneous tissue and fascia (Figure 114-7). The process of undermining tissue minimizes skin tension, allows for eversion of the approximated skin edges, and relieves the extrinsic tension from stitches. **Undermining is performed when the wound cannot be closed due to a tissue defect or if a wound is under tension. This procedure requires the Emergency Physician to be familiar with the local anatomy so that no blood vessels, nerves, or tendons are injured in the process. Do not undermine contaminated wounds.** Undermining large areas can separate the skin from its underlying blood supply and result in a diminished blood flow that predisposes the area to infection and necrosis.⁵⁹ Undermining may be useful on the arm, calf, forearm, forehead, scalp, thigh, and torso. **Never undermine wounds on the face, palms, and soles.**

Undermine tissue at the dermal-epidermal junction or within the subcutaneous adipose tissue. The amount of undermining necessary to close a laceration is approximately double the width of the gap of the laceration at its widest point. Undermine a 1 cm wide laceration for 1 cm on both sides of the wound, including the ends (Figure 114-7). The use of a Mayo scissors versus a #15 scalpel blade to undermine tissue is based on experience and preference. A Mayo scissors is generally recommended as it may cause less secondary injury.

EMERGENCY DEPARTMENT VERSUS OPERATING ROOM MANAGEMENT

Laceration repair may have to be performed in the Operating Room in certain circumstances. Indications for Operating Room repair of lacerations include those associated with other injuries (e.g., neurovascular injuries, open fractures, tendon injuries, and visceral injuries), major or complex wounds involving devitalized tissue or extensive amounts of necrotic or ischemic tissue, heavily contaminated wounds, perineal wounds, large or complicated soft tissue injuries, compartment syndromes, or high-pressure injection injuries.⁶⁰ Consider Operating Room repair or a form of regional anesthesia if the amounts of local anesthetic solution required to repair a wound would exceed toxic tissue levels (Chapter 153).

FIGURE 114-7. Wound undermining. **A.** Sharp undermining with a #15 scalpel blade. **B.** Blunt undermining with a Mayo scissors.

TETANUS PROPHYLAXIS

Worldwide the global incidence of tetanus remains high, although it is comparatively rare in the United States and other developed countries.⁶¹ The reduced incidence in the developed world is due to implementation of large-scale immunization programs, widespread availability of tetanus toxoid and immune globulin, and improved wound care. All traumatic wounds have a potential risk for tetanus infection. Some wounds are more prone to tetanus (**Table 114-1**). The highest risk for developing tetanus in the United States occurs in those with no vaccination, partial vaccination, and patients over 60 years of age (especially if they live in rural areas or are intravenous drug users).

The administration of tetanus prophylaxis is based on the patient's age, immunization history, and the risk of developing tetanus (**Table 114-2**).^{62,63} Current guidelines state that tetanus toxoid (Td) may be deferred in patients with "clean, minor" wounds who have completed a primary series or received a booster dose (i.e., Td 0.5 mL intramuscularly [IM]) within 10 years. Consider tetanus immune globulin (i.e., TIG 250 to 500 U IM) in addition to Td for patients at risk of developing tetanus. Elderly patients without documentation of a primary series, patients from nonindustrialized nations, and those from rural or inner-city areas may never have received tetanus immunization and should be considered for TIG.

ANTIBIOTIC PROPHYLAXIS

An important component of optimizing wound healing is the prevention of infection by copious wound irrigation, removal of foreign bodies, debridement of devitalized tissue, and appropriate wound closure. Wound infections still occur with an incidence

of up to 6.3% despite the best wound care and management.^{64,65}

Most uncomplicated wounds heal without the need for antibiotics. Antibiotics play an important role in prophylaxis of certain high-risk wounds and in the management of wound infections. Determining which wounds have a higher risk for infection and would benefit from antibiotic prophylaxis is an important component of patient management.

Risk stratification for an infection can be performed based on the patient characteristics, wound location, and wound type.¹⁷ **Wounds that have a high risk of infection include bites, wounds that contain foreign bodies, contaminated wounds (e.g., dirt, feces, and soil), crush injuries, wounds involving deep tissues (e.g., open fractures), wounds with a length > 5 cm, and punctures.**¹⁵ Wounds located in poorly vascularized areas (e.g., the extremities) and those with high concentrations of commensal flora (e.g., axilla, groin, or oral mucosa) are also considered high risk. Wounds in well-vascularized tissue (e.g., head, neck, and scalp) are considered low risk. Patient characteristics associated with a high risk of wound infection include diabetes, immunocompromise, peripheral vascular disease, and age over 65 years.

Recommendations and consensus statements agree that low-risk wounds in immunocompetent patients do not require systemic antibiotics.^{12,15,17,66,67} Consider antibiotic prophylaxis when one or more high-risk factors exist (**Table 114-3**). Start antibiotic prophylaxis as early as possible in the Emergency Department. Consider delayed closure to prevent an infection in high-risk wounds.

Topical antibiotics (e.g., bacitracin, mupirocin, neomycin, or polymyxin) are routinely used by many Emergency Physicians. Topical antibiotics in fresh wounds have been shown to decrease the rate of wound infections.⁶⁸⁻⁷⁰ Some experts recommend topical antibiotics for only crush wounds due to the higher risk of infection.⁷¹

TABLE 114-1 Characteristics of Tetanus-Prone and Non-Tetanus-Prone Wounds		
Clinical feature	Tetanus-prone wounds	Non-tetanus-prone wounds
Contaminated with feces, foreign body, saliva, and soil	Present	Absent
Devitalized tissue	Present	Absent
Infection	Present	Absent
Ischemic or denervated tissue	Present	Absent
Mechanism of injury	Burn, crush, bullet	Sharp and smooth (made with glass or a knife)
Wound age	> 6 hours	< 6 hours
Wound depth	> 1 cm	< 1 cm
Wound type	Abrasion, avulsion, crush, irregular, stellate	Linear or straight

TABLE 114-2 Tetanus Prophylaxis		
Immunization history	Tetanus-prone wounds	Non-tetanus-prone wounds
Fully immunized; ≤ 5 years since last dose	None needed	None needed
Fully immunized, > 5 years and < 10 years since last dose	Td	None needed
Fully immunized, ≥ 10 years since last dose	Td and TIG	Td
History of adsorbed Td	Td and TIG	Td and TIG
Unknown or less than 3 doses	Td, TIG, and complete the series	Td and complete the series

Td, tetanus and diphtheria toxoids; TIG, tetanus immune globulin.

TABLE 114-3 Antibiotic Prophylaxis for High-Risk Wounds

Situation	Antibiotic	Treatment days
Dog and cat bites	First dose: parenteral ampicillin-sulbactam, carbapenem, or clindamycin Then: clindamycin plus fluoroquinolone Or Amoxicillin/clavulanate (Augmentin)	3–5
Human bites	First dose: parenteral ampicillin-sulbactam or ertapenem, then Augmentin Or Clindamycin plus fluoroquinolone (sulfamethoxazole-trimethoprim [Bactrim] in children) Or Augmentin	3–5
Intraoral injuries	Penicillin VK or Clindamycin	5
Open fractures	First-generation cephalosporin Add an aminoglycoside for more extensive injuries	1–3

SUTURES

SUTURE TYPES

Suture remains the most commonly used method of approximating open wounds despite the advent of new materials. Properly sized suture material can be summarized as the smallest suture needed to approximate the edges of a wound. Using the smallest size suture that is appropriate for the wound will reduce tissue damage caused by the suture and result in improved cosmesis. The tensile strength of the suture should never exceed the tensile strength of the tissue or it can pull through and damage the tissue (Table 114-4). The sutures should be at least as strong as the normal tissue through which they are being placed.

The size of the suture material is related to the diameter of the suture. The diameter of the strand decreases as the number of 0s in the suture size increases. For example, size 5-0 or 00000 is smaller in diameter than size 4-0 or 0000. Smaller sizes of suture have less tensile strength with decreasing size.

Suture can be classified based on several characteristics including the number of strands that make up the suture, the body's ability to break down the material, and whether they are made of naturally occurring or synthetic materials. Monofilament suture is made of a single strand of material. They encounter less resistance passing through tissue, glide easy through the tissue, and are less likely to harbor organisms that may cause suture-line infections. Monofilaments handle easy and elicit a minimal inflammatory response. Multifilament sutures consist of several filaments or strands twisted or braided together. This affords greater flexibility, pliability, and tensile strength. Bacteria can migrate between the filaments and into the wound.

Another classification is based on the ability of the body to break down and absorb the suture material. Sutures that are digested by body enzymes or hydrolyzed in body tissue and lose their tensile strength within 60 days are considered absorbable sutures. Sutures that maintain their tensile strength for more than 60 days are considered nonabsorbable.⁵⁹ This distinction between absorbable and nonabsorbable is helpful but not completely accurate. Some sutures that are considered nonabsorbable (e.g., nylon and silk) do lose some tensile strength in the 60-day period.⁷²

Absorbable suture can be made of natural or synthetic material. Natural absorbable suture is classified as plain or chromic surgical gut. Plain surgical gut is composed of collagen from bovine or sheep intestine. It is rapidly absorbed, maintains its tensile strength for only 7 to 10 days, and is completely absorbed within 70 days. Chromic gut is plain gut treated with a chromium salt solution to resist body enzymes. It retains its tensile strength for 10 to 14 days and is absorbed over 90 days.

Synthetic absorbable sutures include polyglactin 910 (e.g., Vicryl, Ethicon) and polyglycolic acid (e.g., Dexon). They were developed because of the tissue reaction, suture antigenicity, and unpredictable rates of absorption of natural absorbable sutures. These sutures are braided synthetic materials that retain 50% of their initial strength at 4 weeks. The synthetic absorbable suture retains its tensile strength long enough to ensure the security of the subcutaneous layers after the removal of percutaneous stitches.

Nonabsorbable sutures are made of cotton, linen, metal, nylon, polybutester, polypropylene, or silk. They can be monofilament or

TABLE 114-4 Characteristics of Sutures

Suture	Absorbable	Configuration	Tensile strength	Ease of handling	Knot security	Tissue reactivity	Complete absorption
Glycolide & trimethylene carbonate (Maxon)	Yes	Monofilament	81% at 14 days 59% at 28 days	Fair	Good	Minimal	180 days
Gut, chromic	Yes	Monofilament	Poor at 21–28 days	Poor	Poor	Minimal	90 days
Gut, fast-absorbing	Yes	Monofilament	50% at 3–5 days	Fair	Poor	Low	20–42 days
Gut, plain	Yes	Monofilament	Poor at 7–10 days	Fair	Poor	Moderate	70 days
Polyglactone 25 (Monocryl)	Yes	Monofilament	50%–60% at 7 days	Good	Good	Minimal	91–119 days
Polydioxanone (PDS II)	Yes	Monofilament	70% at 14 days 50% at 30 days 25% at 42 days	Poor	Poor	Low	183–238 days
Polyglactin (Vicryl)	Yes	Braided	75% at 14 days 50% at 21 days	Good	Fair	Low	56–70 days
Polyglycolic acid (Dexon)	Yes	Braided	20% at 21 days	Good	Good	Low	60–90 days
Nylon (Dermalon)	No	Monofilament	Good	Good/fair	Poor	Low	
Nylon (Ethilon)	No	Monofilament	Loses 20% per year	Good/fair	Poor	Low	
Nylon (Nurolon)	No	Braided	Good	Good	Fair	Low	
Nylon (Surgilon)	No	Braided	Good	Good	Fair	Low	
Polybutester (Novafil)	No	Monofilament	Extended	Good/fair	Poor	Low	
Polyester (Dacron, Ethibond, Mersilene)	No	Braided	Indefinitely	Very good	Good	Minimal	
Polypropylene (Prolene, Surgilene, Surgipro)	No	Monofilament	Extended	Good/fair	Poor	Minimal	
Silk	No	Braided	None at 365 days	Excellent	Good	Moderate	

FIGURE 114-8. An example of a knotless suture. Note the barbs on the suture; the looped end does not require knotting.

multifilament in construction. Nylon and polypropylene are the most commonly used suture in the Emergency Department. It is used to approximate lacerations at the skin surface. Silk may occasionally be used in the mouth. Silk can cause significant tissue reactions that result in inflammation and granuloma formation as the body “fights off” this natural fiber. The other types of nonabsorbable sutures are generally not used in the Emergency Department.

Several factors must be considered in choosing suture material (e.g., biologic interaction and mechanical performance).^{12,59} Choose sutures that match the healing properties of the tissues. Approximate slow-healing tissues (e.g., fascia and tendons) with nonabsorbable suture or a long-lasting absorbable suture. Foreign bodies in potentially contaminated tissues may result in an infection. Multifilament suture can act as a foreign body and may convert a contaminated wound into an infected one. Avoid using multifilament suture. Use monofilament sutures or absorbable sutures that resist harboring infection. Use the smallest inert monofilament suture materials (e.g., nylon or polypropylene), avoid using skin stitches alone (i.e., use subcuticular closure whenever possible), and use sterile skin closure strips for apposition when possible. **Use the smallest possible size of the chosen suture type capable of closing the wound to help minimize scarring.**

Knotless suture is commercially available from many manufacturers (**Figure 114-8**). These are referred to as barbed sutures. The barbs are made by placing nicks along the suture and are all in the same direction (i.e., unidirectional) or in two directions (i.e., bidirectional). The barbs allow the suture to be pulled in one direction. Loops at the distal end allow a fixation point in the tissue. The elimination of knots allows weak spots to be eliminated and quicker insertion.⁷³ The elimination of knots improves efficiency. Some of the suture has an antibacterial coating.

Surgical zippers are noninvasive and atraumatic when closing superficial wounds. They are mostly used for surgical wounds but

can be used in the Emergency Department. These devices are simple to apply using adhesive strips. This results in a quick and safe method to close straight wounds. The adhesive zippers work well in areas that move (e.g., over joints). These devices are rarely used now but more experience will increase their use.

NEEDLES

The surgical needle is used to introduce the suture to the skin and help provide the best approximation of the wound edges. Every surgical needle has three components: the swage, the body, and the point. The swaging process serves to provide a smooth junction between the needle and the suture. Needles come with different curvatures, points, and sizes (**Figure 114-9**). The point of the needle extends from the tip and each type is designed to penetrate specific types of tissue. Needles are usually cutting or tapered (**Figure 114-9**). Cutting needles have sharp ends and sharp edges that act as a cutting instrument (**Figure 114-9A**). The cutting needle is commonly used for tougher tissues (e.g., cutaneous, intradermal, and subcutaneous). Conventional cutting needles have a third cutting edge on the inside concave curvature of the needle. This needle type may be prone to “cutout” of tissue because the inside cutting edge cuts toward the edges of the incision or wound.

Reverse cutting needles are as sharp as the conventional cutting needle except that the third cutting edge is located on the outer convex curvature of the needle (**Figure 114-9B**). Reverse cutting needles have more strength than similar-sized conventional cutting needles. The danger of tissue “cutout” is greatly reduced. The hole left by the needle leaves a wide wall of tissue against which the suture is to be tied.

Taper point needles have a pointed end (**Figure 114-9C**). The rest of the needle is a smooth, rounded tube with no cutting edges. This type of needle is commonly used in surgery to close tissues with minimal trauma. It is used for all tissues except skin.

Two other types of needles are often available but not used in the Emergency Department. The blunt point needle has a smooth tip and tapered body (**Figure 114-9D**). It is used for suturing friable tissue and blunt dissection. The taper cut needle has a cutting tip and a tapered body (**Figure 114-9E**). It is a combination of the tapered point and cutting needle. It is used to place sutures through tough tissues. Numerous other needles are available, as are modifications

FIGURE 114-9. Common types of suture needles. **A.** The cutting needle. **B.** The reverse cutting needle. **C.** The taper point needle. **D.** The blunt point needle. **E.** The taper cut needle.

of the five basic needle types. These needles are used by Surgeons for specialized tissues.

Always keep some general principles in mind when suturing. **Pull needles through tissue using a needle driver and never a hemostat.** A hemostat or other clamp can damage the needle. Avoid injury to yourself and others. **Keep all open needles in a place where they will not injure you or your assistant. Account for and discard all suture needles in a “sharps” container.** Following these steps will dramatically decrease the chance for a needle-stick injury.

NEEDLE DRIVERS AND HANDLING SUTURES

Always use a needle driver when suturing. The use of a hemostat or other type of “clamp” can damage the needle and cause it to bend or break in the tissue. Needle drivers are generally made of steel with a jaw designed to hold the needle securely without damaging it. They come in numerous sizes and shapes. Choose a needle driver that is an appropriately sized for the needle that is to be grasped. A 4.5 to 6 inch long needle driver is appropriate for Emergency Department use. Grasp and remove a clean needle from its package with the needle driver. Securely grasp the proximal one-third to one-half of the needle with the needle driver (**Figure 114-10A**). **Do not grasp the distal one-third of the needle.** This can damage its cutting surfaces. **Always use the tips of the needle driver to grasp the needle (Figure 114-10B).** Grasping a needle with the base of the jaws may damage the needle.

Use the needle driver when pushing the needle through the tissue to place a suture (**Figure 114-10C**). **Apply the force in a direction**

following the curve of the needle. This will require pronation and supination of the forearm. Do not twist or force the needle to push the point through the tissue and out the other side. Use a larger needle if the first one is too short or too small. **Do not use a needle that has become dull and difficult to pass through the tissue.** Obtain a new needle and continue the procedure. Grasp the distal tip of the needle with a needle driver when it emerges from the tissues (**Figure 114-10D**). **Always grasp the needle proximal to its distal third to prevent damage to the cutting edges.**

Always use caution when handing a needle driver armed with a needle to another person. Grasp the needle driver between the thumb, index, and middle fingers (**Figure 114-10E**). The needle should be facing away to prevent a needle-stick injury. Hand the base of the needle driver to another person. **Do not blindly pass the needle driver. Do not pass the needle driver over to another person without their knowledge of the transfer. Never grasp the distal end of an armed needle driver.**

Typical needle drivers contained within most disposable, commercially available laceration repair trays are not ideal. The suture often snags on the jaws or hinge when performing an instrument tie. Some needle drivers are designed to be snag-free (**Figure 114-11**).

Suturing lacerations can take a significant amount of time. Much of this time is spent tying knots or switching between instruments (i.e., the needle driver and scissors). Some needle drivers are designed to also cut suture. This decreases the total time required to repair a laceration and avoids the constant switching between instruments.

Most laceration repair trays do not contain suture-cutting needle drivers (**Figure 114-11**). A needle driver and scissors can be simultaneously held in the same hand to improve efficiency (**Figure 114-12**). This technique is favored by many but is initially awkward and requires practice to master. Grasp a scissors with the tip pointing ulnarly (**Figure 114-12A**). Insert the middle finger through the adjacent ring on the handle. Grasp a needle driver in the same hand with the tip pointing radially (**Figure 114-12A**). Insert the thumb and ring finger through the rings on the handle of the needle driver. Grasp a suture needle with the needle driver. Place a stitch and tie it. Remove the thumb from the ring of the needle driver and place it in the open ring of the scissors. Use the thumb to open and close the scissors. Cut off the excess suture (**Figure 114-12B**). Place

FIGURE 114-10. Using a needle driver. **A.** Grasp the proximal one-third to one-half of the needle. **B.** Always use the tips of the jaws to grasp the needle. **C.** Drive the needle through the tissue following the natural curve of the needle. **D.** Grasp the distal needle proximal to the cutting edges. **E.** Correct method to pass a needle driver armed with a needle.

FIGURE 114-11. Examples of snag-free needle drivers. From left to right: The Centurion SnagFree (Centurion Healthcare Products, Howell, MI), the SutureCut needle driver (SutureCut LLC, Lexington, KY), and the Olsen-Hegar needle driver (Henry Schein Inc., Port Washington, NY). The SutureCut and Olsen-Hegar needle drivers have a built-in scissors for suture cutting.

the thumb back into the ring of the needle driver and place the next stitch. Repeat this process until the laceration is closed.

The Alshemari Needle Driver (Alshemari Instruments, Charlotte, NC) holds the needle perpendicular to its length (**Figure 114-13**). This is unlike standard needle drivers. This needle orientation allows for a more comfortable approach and uses vertical, not elliptical, motions to place and tie sutures. The needle driver is used with the hand neutral. The needle driver was designed for otolaryngology procedures in the mouth but can be used anywhere.

WOUND CLOSURE

The goal of wound closure is approximation of the skin under minimal tension while achieving eversion of the wound edges (Chapter 116). Wound eversion slightly raises the wound edges to keep the epidermal cells from migrating into the dermal layers and leaves a flat scar (**Figure 114-14**). **Place stitches closely enough to approximate wound edges but not so tight as to cause tissue necrosis.** The time from the injury to presentation and the mechanism of injury will indicate whether the laceration mandates delayed closure instead of primary closure and whether tetanus prophylaxis is required. Consider high-risk wounds for delayed closure except in patients who are immunocompromised or taking immunosuppressive therapy.

SINGLE-LAYER VERSUS MULTILAYER CLOSURE

The greatest strength of the skin, and of the wound, is contained within the dermis. The narrower the scar, the better will be the coaptation of the dermal edges. The best results occur when the

entire depth of the dermis is accurately approximated to the entire depth of the opposite dermis. Dermal closure is best performed with synthetic monofilament absorbable suture that requires enzymatic degradation (e.g., Vicryl). Chromic or plain catgut suture dissolves much more rapidly by means of hydrolysis.

Close the wound in multiple layers to better approximate the edges and improve cosmesis. Close the wound with a minimal number of stitches in a single layer if the goal is a functional result. **Do not suture through fat and muscle.** Fat has no tensile strength. Stitches placed tightly in fat can cause ischemia and necrosis in the wound and increase the risk of a wound infection. Muscle fibers do not support suture. Muscle is best treated by repair of the overlying fascia, immobilization to prevent motion, and natural coaptation of the muscle fibers.

Wounds may cross tissue planes to open them and create potential pockets or dead spaces. Elimination of the dead space has been advocated in the past to decrease the probability of this area becoming a nidus for infection. This once traditional practice of obliteration of dead space to avoid infection of a nonvascularized space or to prevent hematoma formation is now considered controversial. Animal models have found the incidence of infected wounds to be consistently proportional to the number of suture layers.^{74,75} Leaving dead space open resulted in lower rates of infection than obliterating

FIGURE 114-13. The Alshemari needle driver (Alshemari Institute, Charlotte, NC).

FIGURE 114-14. Eversion of the wound edge signifies proper suture placement and knot tension.

it with sutures.^{74,75} Studies in 1994 and 1996 concluded that buried absorbable sutures increase the infection rate, increase the degree of inflammation in contaminated wounds, and do not significantly increase the degree of inflammation in noncontaminated wounds.⁷⁶ Stitches placed in fat contribute no strength to the repair and fail to prevent hematoma formation and infection. **Deep absorbable stitches may be placed to repair fascia, muscles, or periosteum. Deep absorbable stitches minimize tension on skin stitches. Use only enough subcutaneous stitches to restore anatomic and functional integrity.** Leaving a potential space may be preferable to attempting to obliterate it.

STERILE GLOVES

It is a common practice to wear sterile gloves when repairing a laceration. The advantages of sterile gloves include a better fit, improved dexterity, and improved tactile sensitivity. The use of sterile gloves for laceration repair costs significantly more than using nonsterile, clean gloves from a box. Boxed, clean, nonsterile, and powder-free examination gloves can be used for uncomplicated wound repair in immunocompetent patients. No clinically important differences in infection rates have been found when comparing sterile gloves to clean gloves in this setting.⁷⁷⁻⁷⁹

The use of clean gloves from a box is not always ideal. Clean gloves come in a limited number of sizes (i.e., extra-small, small, medium, large, and extra-large). The fit and feel of clean gloves may not be as comfortable for the Emergency Physician. Clean gloves may have more manufacturing defects when compared to sterile gloves.⁸⁰ These defects can result in the loss of personnel protection and the potential to contaminate the wound. Others have shown clean gloves to have comparable quality to sterile gloves.⁸¹⁻⁸³ A box of clean gloves that has become wet can harbor mold.⁸⁴ The decision to wear clean versus sterile gloves is up to each Emergency Physician.

WOUND CLOSURE PROCEDURE

Thoroughly clean any blood, debris, and dirt from the skin. Scrub the skin surrounding the wound with an antiseptic skin cleanser (e.g., povidone iodine or chlorhexidine). Anesthetize the wound with a 27 to 30 gauge hypodermic needle and local anesthetic solution. Irrigate the wound with normal saline. Use a mask with a face shield to prevent exposure to the patient's blood and tissue fluid. Debride and undermine the wound as necessary. Irrigate the wound again to remove exposed debris and devitalized tissue. Repair the wound with sutures or pack it with saline-soaked fine-mesh gauze for delayed closure. Clean the repaired wound with normal saline and apply a dressing for comfort and protection. Consider the application of a splint for wounds across joints or muscle lacerations.

Write a procedure note describing the sterile preparation of the wound, the type and volume of anesthesia administered, the type and number of stitches used in the repair, the layers repaired, the type of repair (i.e., interrupted versus continuous), and how the procedure was tolerated by the patient. Note any complications.

AFTERCARE

Wound care has become a specialty involving sophisticated research in many areas, including dressings and the environment in which wounds heal best. Optimal growth of fibroblasts in tissue culture occurs at low partial pressures of oxygen (e.g., 5 to 10 mmHg). Epidermal cell growth is inhibited at oxygen levels higher than surrounding air. Hydrocolloid dressings can maintain an environment of low oxygen tension independent of the underlying disease process.⁸⁵ A wound surface will be cleansed with saline after laceration repair

to remove any residual blood and debris before a dressing is applied. The application of an occlusive dressing has been shown to increase the rate of wound healing by approximately 40%, keeps bacteria out of the wound, and prevents environmental trauma. A similar infection rate was found for wounds that were closed by primary intention with and without a dressing.⁸⁶ A dressing is generally recommended in wounds left to heal by secondary intention. There is not enough evidence to recommend one dressing over another.⁸⁷

Dressings, regardless of the type used, should produce a moist wound that is free of foreign material, infection, and toxic chemicals. Layered dressings of nonadherent gauze (e.g., Xeroform) can be covered with dry gauze for large sutured lacerations and abrasions. This dressing draws exudate into a layer that can be replaced without disturbing the underlying wound. Shear wounds or hematomas may require gauze that is fluffed and formed into a pressure dressing. Dressings of antibiotic ointment with a standard adhesive bandage (e.g., Band-Aid) provide adequate healing and protection for smaller repaired lacerations. The application of topical antibiotics to the suture line after wound closure may help protect against exogenous bacterial contamination. A Cochrane database systematic review of surgical incisions has shown that topical antibiotic application may reduce wound infection at surgical sites relative to antiseptics or no antibiotics.⁸⁷ The preferred topical antibiotic is not clear in this review. There is no evidence that topical antibiotics are harmful and are generally recommended.⁸⁸

DISCHARGE INSTRUCTIONS

Evaluate high-risk wounds (e.g., animal bites, human bites, hand wounds, heavily contaminated wounds, and wounds that require prophylactic antibiotic coverage) within 24 hours. Make patients aware, orally and in writing, that up to one in 10 patients develop a wound infection that can be treated with an oral antibiotic. Puncture wounds are considered high-risk injuries that can result in bone infections and follow-up instructions are essential. Patients should be instructed to immediately return to the Emergency Department or their Primary Physician if a wound becomes red or has a discharge, if redness or red streaks are emanating from the wound, or if they develop a fever. Getting sutures wet in the first 48 hours does not affect the infection rate or tensile strength.⁸⁹ Inform the patient that it is alright to wet the stitches but not soak them while the wound is healing.

Discharge instructions should be simple and precise with important points emphasized and reiterated. Patients have been shown to have knowledge deficits regarding home care and return instructions.⁹⁰

Explain briefly the progression of healing. The new scar's appearance is usually worst at 3 to 5 weeks. Most scars remodel within 6 to 12 months. Postpone any revision of the wound for at least 6 to 12 months from the time of injury.

STITCH REMOVAL

The length of time that the stitches remain in place depends on the location of the wound, the amount of tension on the wound, and the healing time of the involved tissue. General recommendations are listed in **Table 114-5. Appropriate and timely removal of stitches minimizes scarring.** Full-thickness stitches can be left in place for 2 or more weeks without risk of suture-track formation in areas where sebaceous glands and other adnexal structures are not present (e.g., palmar and plantar surfaces). Leaving stitches in place too long results in epithelialization of the suture tracts, larger scars, and possible infections. Suture removal kits are commercially available. They typically contain a metal or plastic forceps, a scissors,

TABLE 114-5 Suture Removal Recommendations

Location	Days
Back	10–14
Buttocks	10–14
Chest	7–10
Delayed closure	8–12
Foot	10–14
Face	3–4 (child), 3–5 (adult)
Hand	10–14
Legs	8–10
Neck	2–3 (child), 3–4 (adult)
Overlying joints	10–14
Retention sutures	14–30
Upper extremity	7–10

and a few gauze squares. These kits are inexpensive, disposable, and intended for single-patient use.

Remove stitches using aseptic and sterile technique. Clean the wound with saline. Apply hydrogen peroxide to remove any dried blood and serum encrusted around the suture. Grasp the suture strand at the knot with forceps (**Figure 114-15**). Lift the knot off the skin. **Cut the one strand of the suture as close to the skin as possible with a scissors and where the suture enters the skin (Figure 114-15).** This will avoid drawing contaminated suture through the depth of the wound. Stitches that are close together, small, or tight may require a #11 scalpel blade to cut them rather than a scissors. Gently pull the suture strand out of the tissue with the forceps and across the wound. Pulling a suture out and away from the wound may result in the wound edges opening (i.e., dehiscing). **Remove one to three stitches and ensure that the wound edges do not dehisce.** Remove the remaining stitches if no dehiscence occurs. Apply skin adhesive strips (e.g., Steri-strips) across the wound to provide support. **Leave the stitches in for a few more days if there is any doubt about adequate tensile strength of the wound and possible dehiscence.** There are few data regarding the effect of advanced age and steroid use on exact timing of removal. Conservative management suggests leaving stitches in these patients longer than in potentially faster healing groups. There is evidence that a select group of patients (e.g., over 19, immunocompetent, simple lacerations) may be willing and capable of removing their own stitches.⁹¹

MANAGEMENT OF PUNCTURE WOUNDS

Puncture wounds are considered higher risk for infection than simple lacerations. They should be allowed to heal by secondary intention if small or delayed and primary intention if closure is required because they are large or for cosmetic reasons.⁹² Local cleansing is the initial step in management. High-pressure irrigation, coring, and probing are generally not recommended.

Infection is most frequently due to *Staphylococcus aureus*, *Staphylococcus epidermidis*, or streptococcal species. Treatment should be

FIGURE 114-15. Stitch removal.

reserved for immunocompromised hosts, dirty wounds, or infected wounds.⁹³ Puncture wounds of the foot are of special concern due to the risk of *Pseudomonas aeruginosa* infection, particularly with wounds through athletic shoes. A tender wound that is not infected may indicate that there may be a retained foreign body. Persistent infection from a plantar wound suggests an underlying infection and possibly osteomyelitis that requires a further work-up and treatment with antibiotics that may include fluoroquinolones.⁹⁴

WOUND HEALING IN THE PEDIATRIC PATIENT

Pediatric patients less than 15 years of age experience infection rates of less than 1% for clean surgical wounds.¹² This is less than that seen in adults. Children will sometimes require sedation to make painful or difficult procedures possible. Safe and effective procedural sedation (Chapter 159) for patient comfort or cooperation can facilitate or expedite medical care. Undermining is not useful in most pediatric wounds as they do not usually require advancement of skin over a significant tissue defect. Scalp lacerations account for 30% of pediatric lacerations. Scalp lacerations are well suited for single-layer repair with staples. Cosmetic results are comparable with those of sutured repairs, with no differences in complication and infection rates. Laceration repair with staples is faster, less expensive and can be implanted rapidly and accurately in a moving child.⁹⁵

ALTERNATIVE CLOSURES

Alternative methods of wound closure include skin closure tapes, staples, and tissue adhesives. These are mentioned briefly below. A more complete discussion can be found in Chapters 116 and 117.

SKIN CLOSURE TAPES

Skin closure tapes are adhesive strips used to approximate wound edges. Adhesive-backed long and narrow strips are used for approximating the edges of lacerations with or without staples or sutures and for closing the skin following many operative procedures. The most common type is the Steri-Strip. Skin closure tapes are felt to develop and increase wound tensile strength faster than sutured wounds because uniformly orienting collagen fibers apply equal stress across the wound. Skin closure tapes are porous which allows for good air inflow and the escape of water vapor during the healing process. Strips are placed perpendicular to the wound in conjunction with an adhesive (e.g., Mastisol or tincture of benzoin). **Take care not to get adhesive in the wound.** There is the option of placing Steri-Strips on thin-skinned individuals and then suturing through both the thin skin and overlying Steri-Strips (**Figure 114-16**). This increases the tensile strength of the skin and minimizes the chance of the stitches ripping through the thin skin.⁹⁶⁻⁹⁸

There are numerous advantages and disadvantages to using skin closure tapes. They prevent local skin tension, wound infections, and “railroad track” scarring on the skin. Skin strips maintain equal tension along the length of the laceration if applied correctly. Application reduces time and costs when compared to suturing. The disadvantages include loss of adhesiveness over time, wound dehiscence, difficulty with apposition of skin edges, difficulty in evert-ing the wound edge, and are dependent on the knowledge and skill of the Emergency Physician. Injuries to the skin can occur during placement or removal.

TISSUE ADHESIVES

Tissue adhesives (e.g., butylcyanoacrylate and octylcyanoacrylate) are viable alternatives to standard wound closure techniques using

A

B

FIGURE 114-16. Suturing through Steri-Strips. **A.** Artist illustration. (Used with permission from reference 96.) **B.** A leg wound with the technique. (Used with permission from reference 98.)

skin tapes, staples, or suture for closure of simple lacerations. It has been clinically proven that there is no difference 1 year after treatment in the cosmetic outcome of wounds repaired with sutures versus those closed with octylcyanoacrylate tissue adhesive.⁹⁹ There is no difference in cosmesis when comparing various tissue adhesives for traumatic laceration closure. There is a slight increase in wound dehiscence when comparing tissue adhesives with standard wound closure techniques.¹⁰⁰ The disadvantages are minimal (i.e., cost, proper patient selection, and meticulous technique). They save time when compared to suturing and are easy to use. There is no risk of a needle-stick injury and no need for follow-up visits for removal.

STAPLES

Staple closure is time efficient compared to the suture repair of lacerations.¹⁰¹ It is primarily used for large wounds that are not on the face, feet, hands, or neck. Stapling is especially useful for closure of incisions in the extremities, hair-bearing skin (i.e., the scalp), and the trunk. The wound edges require manual eversion with forceps prior to placing the staples. Staples are effective for straight wounds

and are rapid to place. Staples may cause scarring, skin irritation, and wound contamination and may require removal.

SUMMARY

Expert wound management consists of attention to the details surrounding the wound, gleaned important information concerning the patient's history, and meticulous wound preparation. Attention to the possibility of foreign bodies, underlying injury to anatomic structures of significance, and the risk of subsequent wound infection should all be foremost in the Emergency Physician's mind when managing wounds in the Emergency Department. Educate the patient about the possible outcomes of wounds and lacerations and encourage appropriate follow-up.

Burn Wound Management

Stephen Sandelich and Christopher J. Russo

INTRODUCTION

Injuries secondary to burns represent a significant and prevalent form of injury with major morbidity and mortality. **Prevention must still be in the forefront of burn management.** There has been an increase in the prevalence of a shift to ambulatory or Emergency Department care for burn patients.¹⁻³ Scald burns make up the majority in children younger than 5 years of age with the balance shifting to flame burns in older children. The rates of hospitalization

for burns appear to be decreasing.⁴ The annual cost for burn hospitalizations exceeds \$200 million per year.⁴

Child abuse must be considered in all pediatric burn patients. Abuse should be suspected in younger patients presenting with burns that are in a bilateral and symmetrical distribution (e.g., a stocking and glove distribution), patterned burns (e.g., a hot grate), or burns on the dorsum of the hands; in cases of delayed medical care; or when there are inconsistent histories.

The Emergency Physician must be familiar with the initial management of burns, the treatment of burns, and the indications for transfer to a regional burn center. This chapter is limited to minor burn management of the skin as an outpatient. It will not cover airway burns, significant burns, fluid and electrolyte management, associated poisoning (e.g., carbon monoxide and cyanide), and inhalation burns.

ANATOMY AND PATHOPHYSIOLOGY

The skin is the largest organ of the body. It consists of the epidermal, dermal, and subcutaneous layers (**Figure 115-1**). The epidermis is the outer layer of stratified squamous epithelium, whereas the dermis is a dense bed of vascular connective tissue. The skin acts as a physical barrier, a sensory organ, and a thermoregulatory organ. The body reacts to a burn with local and systemic responses.

There are three zones of tissue response described after an acute thermal injury.⁵ The zone of coagulation occurs at the point of maximum damage. Tissue proteins coagulate and lead to irreversible tissue loss. The next zone is labeled the zone of stasis and is characterized by decreased tissue perfusion. This tissue may be salvaged or completely lost if not properly treated. Surrounding the zone of stasis is a zone of hyperemia. This area sees an increase in tissue perfusion. Tissue in this zone should recover unless there are severe systemic insults (e.g., profound hypotension or sepsis). Severe and major burns can involve a systemic response (e.g., cardiovascular, respiratory, metabolic, and immunologic derangements). Systemic involvement is generally not seen unless a burn is greater than 20% of body surface area (BSA).⁶

Burns are classified by depth, size, and total body surface area (TBSA) involved.^{7,8} A superficial or first-degree burn is characterized by dry, blanching, and erythematous skin. This is accompanied by a mild inflammatory response without bulla formation. These burns are usually painful and will heal quickly over the course of 3 to 6 days without scar tissue formation. The outer epithelial layer will peel away from the newly forming layers underneath. It has been compared to a bad sunburn.

Partial-thickness, or second-degree, burns may be either superficial or deep. A superficial partial-thickness burn has destroyed the epidermis but does not penetrate fully through the dermis. A deep partial-thickness burn will extend deeper into the dermis. Superficial burns will form blisters quickly within 24 hours. Edema will be present from increased capillary permeability that occurs from direct thermal injury. These burns are very painful as the nerve endings in the dermal tissue are exposed. They appear erythematous or pink, moist, and blanch with pressure. Deep partial-thickness burns will blister and are often insensate. The burn has destroyed most of the dermal layer and the nerve endings along with it. Deep burns are variable in color (e.g., erythematous to white), appear drier than superficial burns, and do not blanch with pressure.

Full-thickness or third-degree burns have penetrated the entire epidermis and the dermis. They are pale or charred, appear leathery, and are white or black. They are insensate and not painful. There is no capillary refill and the area has red dots from the red blood cells in the capillaries rupturing. The edema will not be as apparent because the tissue has lost much of its elasticity and cannot stretch as readily.^{9,10} These burns cannot form new epithelial tissue and will

FIGURE 115-1. Cross section of the skin.

most often require skin grafting. It may be difficult to fully classify burns in the acute phase because the full extent of damage may not be apparent until a few days after the original burn.¹¹

Accurate estimation of burn size remains important as this can direct management decisions regarding fluid resuscitation and the need for transfer to a burn center.¹² Large burns are often underestimated, resulting in delayed transfer and lack of adequate fluid resuscitation. The two commonly used methods of estimation of burn size are the rule-of-nines (**Figure 115-2**) and the Lund-Browder chart (**Figure 115-3**). The Lund-Browder charts are preferred in children as they account for the relative differences in the body area as the child ages and the proportionately larger heads in children. Smaller burns or burns with patchy areas can also be estimated using the palmar method in which the patient's entire palmar surface is assumed to be equal to approximately 1% TBSA.

INDICATIONS

Minor burns that can be cleaned, dressed, and followed in an outpatient setting include partial-thickness burns less than 5% TBSA in children younger than 10 years old, partial-thickness burns less than 10% TBSA in children older than 10 years old, and full-thickness burns less than 2% TBSA. Burns with areas larger than this should be considered major burns. Consider transfer of more extensive burns to a regional burn center.

CONTRAINDICATIONS

Burns involving the face, hands, perineum, or feet; burns crossing major joint lines; and circumferential burns are considered major burns. Refer these patients to a burn center. **Table 115-1** lists the

burns that should be transferred to a burn center.¹³ Patients who present with multisystem trauma require stabilization prior to attending to burn care.

EQUIPMENT

- Mild soap
- Warm water
- Topical antibiotics
- Silver impregnated dressing
- Nonadherent dressing (e.g., Adaptic or Xeroform)
- Layered dry gauze (e.g., Karlie)

PATIENT PREPARATION

Explain the procedure to the patient and/or their representative. An informed consent for the care of burns is not required. Obtain an informed consent for any anesthetic technique performed and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Update the patient's tetanus immune status if required.

Burns are generally exquisitely painful injuries and adequate analgesia should be achieved prior to any painful procedures (e.g., debriding or burn dressing application).¹⁴ Small superficial burns are adequately managed with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen. The patient will require more aggressive directed pain management with more severe burns. This

FIGURE 115-2. The rule-of-nines to estimate burn area. (Used with permission from Tauro University.)

can include opioid analgesics (e.g., morphine or fentanyl), nonopioid analgesics, nitrous oxide (Chapter 128), dexmedetomidine, ketamine, or anxiolytics. The patient with significant burns may require procedural sedation and analgesia (Chapter 159) for the initial evaluation and management.

TECHNIQUES

GENERAL MANAGEMENT

Perform an initial assessment. Remove any clothing and jewelry from the affected areas. Remove any rings as these will be difficult to remove once edema occurs. Cool the affected area. Perform cooling within the first 30 minutes after the injury. Early cooling may reduce the ongoing thermal injury and the development of progressive edema. The water should be cool while avoiding ice or ice water.^{15,16} Cooling should progress until pain is diminished and not for longer than 5 to 10 minutes. Clean the wounds with a mild antibacterial soap. First-degree burns require no further management. Instruct the patient to continue washing the affected area with mild soap and warm water daily until full healing has occurred.

FLUID RESUSCITATION

Most minor burns treated as an outpatient do not have fluid and electrolyte shifts. Most burns less than 20% BSA do not need fluid resuscitation. Start with crystalloid solutions if fluid is required.¹⁷ The most commonly used formulation is the Parkland formula (Table 115-2). Some institutions use the Cincinnati-Shriner or

Brooke formula (Table 115-2). These fluids represent the volume to be given in 24 hours from the time of the burn and not the clinical presentation. Divide the total volume calculated in half. Administer the first half over the first 8 hours followed by the second half over the next 16 hours. These calculations represent an estimate for resuscitation. They do not include base hydration and other losses. A further discussion is beyond the goals of this chapter.

DEBRIDEMENT

Intact blisters (Figure 115-4A), ruptured blisters, and devitalized tissues represent a nidus for future bacterial infection and should be carefully removed. This is usually a painful procedure and will require some type of pain mitigation strategy. This may include oral analgesics, local or regional nerve blocks (Chapter 156), intravenous regional anesthesia (Chapter 157), nitrous oxide (Chapter 158), or procedural sedation and analgesia (Chapter 159).

Remove the nonviable tissue with gentle traction, scraping, and cutting (Figures 115-4B and 115-4C). Blister management is somewhat controversial.^{18,19} Remove all ruptured blisters as the dead epithelial layer may increase infection rates and delay wound healing. Burn blisters that have not ruptured may be managed in multiple ways. There is no gold standard to guide practice. One practice leaves the blisters intact in the belief that they represent superficial injury and will heal spontaneously if left undisturbed. The blister protects the wound with its own biological dressing. There is some thought that the burn blister fluid may stimulate the wound-healing process through expression of various growth factors found in the exudate.²⁰ The opposing camp believes that the

blister fluid may depress immunologic functioning of the underlying new epithelial layer, delay total healing time, and provide a culture medium for bacterial growth. Most evidence appears to suggest that best healing results are achieved with leaving blisters intact unless they are large and thin-walled blisters that may rupture during the healing process. **Needle aspiration of a burn blister should generally not be performed as this can increase the risk of infection.** The exception to this is larger thick-walled blisters that are overlying a joint.⁹

TOPICAL ANTIBIOTICS

The decision must be made regarding the need for topical antibiotic coverage. The goal of these dressings is to relieve pain and to promote healing. Superficial burns with an intact dermis have a

very small risk for bacterial infection and topical antibiotics are not indicated. These wounds can be effectively managed using a non-perfumed moisturizing cream or aloe vera.²¹ Wounds that extend deeper into the dermis are at a higher risk for infection. Apply topical antibiotics before applying the final dressing. The choice of topical antibiotics depends on the patient, the provider, the type of burn, any patient allergies, regional preference, and individual preference.

Silver sulfadiazine (SSD) is one of the most common topical burn treatments available (**Figure 115-4D**).²²⁻²⁴ SSD is a nontoxic salt of silver sulfadiazine in a water-based cream. It is painless and has a wide spectrum of antimicrobial action and a long shelf life. It is available as a thick white paste that is applied over the burn and covered with a nonadherent dressing. The SSD dressing can be reapplied up to three times a day until healing occurs. SSD is contraindicated in patients with a sulfa allergy, pregnant women,

lactating women, and newborns.²⁵ SSD decreases the amount of bacterial colonization and decreases infection rates. It may prolong wound healing through inhibition of keratinocyte replication and increase the frequency of required wound dressing changes. There are multiple silver-impregnated dressings available for burn care (e.g., Aquacel AG, Mepilex AG, and Acticoat).^{24,26} They have been shown to result in faster healing times, decreased pain, decreased dressing changes, and improved patient satisfaction and to reduce overall costs.²⁷⁻³¹

Some burns are not treated with SSD. Superficial facial wounds are often treated with a clear antibiotic ointment such as bacitracin. The silver preparations can cause cosmetic staining of the skin. Triple antibiotic ointment on deep full-thickness pig skin burns enhanced reepithelization, decreased scar depth, and decreased scar contraction compared to silver preparations.³² This has not been proven in humans yet. Wounds that are near the eye should be treated with a topical ophthalmic ointment. Systemic prophylactic antibiotics are not required in most burn patients.³³

WOUND DRESSING

Cover the burn with layered gauze or a nonadherent dressing and secure it (**Figures 115-4E and 115-4F**). No dressings should be applied if the burn is deep or meets burn center transfer criteria (**Table 115-1**). The dressing will need to be removed once the patient reaches the burn center. This will cause the patient more pain and local trauma to the tissues. Cover the burns with dry gauze or a nonadherent dressing and a clean dry sheet. The best outcomes are achieved with a quick transfer to the burn center.

The burn can be covered with ChloroDerm (Entrotech Life Sciences, San Francisco, CA) if the patient is being discharged from

the Emergency Department. ChloroDerm was approved for use on burn wounds in early 2016. It is transparent, safe, and can be left on for 7 days. It contains an acid-free chlorhexidine matrix and is cost-effective. It resists the growth of bacteria, fungi, and viruses that can cause infections.

PEDIATRIC CONSIDERATIONS

Children are often excellent patients for outpatient management of their burns.^{34,35} The ability of the parents or caregivers to adequately perform the burn dressing changes must be ascertained. It can be beneficial to select a dressing that can stay in place for 7 days (e.g., Mepilex AG or ChloroDerm) to avoid the parent having to perform a painful dressing change at home.^{36,37} **Pay specific attention to pain and anxiety control in the pediatric patient.** Adjuncts to classic pharmacologic treatments (e.g., distraction and child life providers) can significantly improve the initial evaluation and wound dressing.

AFTERCARE

Instruct the patient and their caregivers on the instructions for proper burn dressing change management, pain control, and infection prevention. The primary care physician may be competent to complete adequate follow-up of minor or superficial burns. Follow-up in a certified burn center is more appropriate in deeper burns, burns in younger children, or burns on concerning areas of the body. Superficial burns will heal completely in 3 to 6 days, whereas a superficial partial-thickness burn may take between 7 and 20 days for full healing. Superficial burns do not require dressings and may be managed with daily washing with warm water and gentle soap. Moisturizing lotion and aloe vera may be applied to the burned area to provide comfort. The frequency of dressing changes depends on the type of burn and the type of dressings chosen. Daily changes appear to show no change in morbidity and lead to less pain than multiple changes per day.^{22,37} Firm recommendations regarding an optimal number of dressing changes do not exist. Manage these burns as a healing superficial wound with a moisturizing cream or aloe vera once the epithelial layer has been replenished.

COMPLICATIONS

Complications can include inadequate pain control, infections, and/or increased scarring. Most superficial burns will heal quickly and may only need NSAIDs or acetaminophen for adequate pain control. Deeper or more extensive burns may require opiate narcotics to gain adequate pain control. A longer acting analgesic may be needed if the current management is not temporally extending long enough. A dressing requiring less frequent changes may be considered if pain is centered mostly around dressing changes. Anxiety may lead to increased perception of pain in the pediatric population and must be adequately addressed. More than 90% of patients will experience a significant amount of pruritus that can be interpreted as pain, especially in young children. Scheduled antipruritic agents (e.g., diphenhydramine) may be helpful to counteract the pruritus.

Infection is a serious complication. It is a rare complication of most superficial or partial-thickness burns. Infection can greatly delay wound healing or scar formation. Prophylactic oral antibiotic therapy has been shown to be ineffective in preventing infections in the burn patient. A local cellulitis may develop as the patient's normal skin flora recolonizes the area. Cellulitis can be effectively managed as an outpatient with a first-generation cephalosporin if

TABLE 115-2 Formulas Commonly Used in Fluid Resuscitation of Burn Patients

Name of formula	Fluid	Total volume (mL in 24 hours)
Parkland	Lactated Ringer's	$4 \text{ mL/kg} \times \text{weight (kg)} \times \% \text{BSA of burns}$

there are no signs or symptoms of systemic spread of the infection (e.g., fever, chills, nausea, or emesis).

SUMMARY

Most burn patients can be effectively managed as an outpatient. Most minor burns will heal well with minimal care or intervention. Patients with deep burns, burns that cover a large surface area, burns of the hands or feet, or burns that cross major joint lines should be transferred to a burn center for definitive management (**Table 115-1**). Most superficial burns can be treated with moisturizer and gentle cleansing. Deeper burns should be debrided and a topical antimicrobial dressing applied. Monitor healing for signs of developing infection. Management of pain and pruritus in these patients remains important.

Basic Wound Closure Techniques

Eric F. Reichman

INTRODUCTION

Wound management is crucial to the practice of Emergency Medicine. Emergency Physicians routinely care for wounds ranging from simple lacerations to complex injuries in the trauma patient.¹⁻⁶ Wound repair is always secondary to the evaluation and stabilization of any life-threatening and limb-threatening emergencies. However, patients are often legitimately concerned about the outcome of wounds and lacerations. There are several basic suture principles that will help to provide optimal wound healing and ensure a more than acceptable cosmetic result. The previous chapter outlines the essential principles of wound management. This chapter describes the basic methods used to close wounds.

SUTURES

The choice of suture materials is important in wound closure. Sutures are made of a wide variety of materials, both natural and synthetic. Natural substances include gut made from sheep and beef, cotton, and silk. **Natural substance sutures cause more tissue reactions and scarring, which limits their use.** Cotton sutures are not discussed, as they are no longer used in clinical practice. Synthetic sutures can be made of nylon, polyethylene (e.g., Dacron), polyglactin (e.g., Vicryl), polypropylene (e.g., Surgilene and Prolene), polyglycolic acid (e.g., Dexon), poliglecaprone (e.g., Monocryl), polydioxanone (e.g., PDS), polyglyconate (e.g., Maxon), and metal.⁶ Metal sutures are used in the Operating Room and not in the Emergency Department as they are difficult to handle, prone to breakage, and indicated in only a few situations. Synthetic sutures tend to have a problem with “memory.” That is, they tend to retain the shape of their packaging. This can make it difficult to manipulate the suture during wound closure.

Sutures are constructed as monofilaments or polyfilaments. Polyfilament fibers consist of multiple single filaments braided together to form one suture. They are easier to handle than monofilament sutures, as they tend to be more pliable. Polyfilament sutures have better knot security and therefore reduce the incidence of knot slippage. However, they can be associated with a higher incidence of infection than monofilament sutures. They allow bacteria to migrate (or wick) between the strands of the suture located at the skin surface and into the wound.

Select the smallest diameter suture that can adequately hold the tissue edges together in order to reduce tissue damage and scarring. The largest suture material available is size #5. The suture sizes decrease to zero (i.e., #4, #3, #2, #1, #0) and then are followed by #00 (i.e., 2-0), #000 (i.e., 3-0), and #0000 (i.e., 4-0) in decreasing size. The smallest suture commonly used in the Emergency Department is 6-0 for facial lacerations, nail bed lacerations, and lacerations in cosmetically sensitive areas. The tensile strength of sutures is related to their size. The tensile strength of suture increases as the size increases. For example, 4-0 is stronger than 5-0.

The other main category of suture classification is absorbable versus nonabsorbable. In the past, absorbable sutures were primarily used to close the subcutaneous layers of a wound. More recently, absorbable sutures have also been used for skin closure. Nonabsorbable sutures are primarily used for skin closure.

ABSORBABLE SUTURE MATERIALS

Absorbable sutures are degraded by the body and do not require removal. They usually do not maintain their tensile strength for

TABLE 116-1 Absorbable Suture Materials

Suture type	Source	Tensile strength	Tissue reaction	Knot security	Absorption
Plain surgical gut	Beef or sheep collagen	Poor	Moderate	Poor	1–2 weeks
Chromic surgical gut	Beef or sheep collagen	Poor	Moderate	Fair	2–3 weeks
PolySyn FA	Polyglycolic acid	50% remains at 5 days; 0% at 14 days	Minimal	Good	7 weeks
Monocryl	Polylicaprone 25	20% remains by 3 weeks	Minimal	Good	3 months
Caprosyn	Polyglytone 6211	60% remains at 5 days; 30% at 10 days	Minimal	Good	2 months
Coated Vicryl	Polyglycolic 910, polyglactin 370, and calcium stearate	65% remains at 2 weeks; 40% at 3 weeks	Minimal	Fair	3–6 months
Dexon	Polyglycolic acid	50% remains at 4 weeks	Minimal	Good	3–4 months
Vicryl Rapide	Polyglactin 910	50% remains in 5–6 days	Minimal	Good	42 days
PDS polydioxanone	Polyester polymer	70% remains at 2 weeks; 50% at 4 weeks	Slight	Poor	6 months
Maxon	Polyglyconate	50% remains at 7 weeks	Slight	Fair	6 months
V-Loc 90	Glycolide, diaxanone, and trimethylene carbonate	90% remains at 7 days, 25% at 14 days	Minimal	N/A	90–110 days
V-Loc 180	Glycolic acid and trimethylene carbonate	65% remains at 21 days	Minimal	N/A	180 days

longer than 60 days. Body enzymes dissolve the absorbable sutures with the aid of an inflammatory reaction. The rate of absorption of the sutures varies based upon the tissue where it is placed, the composition of the suture, and the size of the suture. Absorbable sutures placed in mucous membranes absorb faster than those placed in muscle tissue or fascia. Smaller sizes of suture dissolve faster than larger sizes.

There are several types of absorbable sutures, both natural and synthetic (**Table 116-1**). The most commonly used absorbable sutures in the Emergency Department are plain gut, chromic gut, polyglycolic acid (e.g., Dexon), polyglactin (e.g., Vicryl), and Vicryl Rapide. Plain gut and chromic gut are both natural forms of absorbable sutures. They are made from the intestines of sheep and cattle. Gut is a tissue irritant and can cause a substantial tissue reaction while it is being absorbed and degraded by the body. Chromic gut is plain gut that has been soaked in chromic acid salts. This process helps to extend the half-life of the suture and allows it to maintain its tensile strength longer than plain gut. Chromic gut may retain its tensile strength for 2 to 3 weeks, while plain gut retains its tensile strength for 1 to 2 weeks. Both types of gut are packaged wet in order to keep them from drying out and becoming too stiff.

Synthetic absorbable sutures, such as Dexon and Vicryl, are typically used more often than natural absorbable sutures in the Emergency Department. They are degraded by the body more slowly than natural fibers and can therefore help maintain the strength of the wound longer. Vicryl and Dexon maintain their tensile strength at 80 days and 120 days, respectively. They cause less reaction in the tissues as they break down when compared to natural absorbable sutures.

Absorbable sutures have gained some popularity for use in skin closure.⁷⁻¹² Absorbable sutures have been shown to yield equal results in their rate of dehiscence, rate of infection, and cosmesis when compared to nonabsorbable sutures.⁷ Absorbable sutures have the added benefit for the patient of not having to return to have their sutures removed. Vicryl Rapide is a newer form of Vicryl that is especially suited for this purpose. This type of suture is rapidly absorbed. They begin to fall off in 7 to 10 days as the wound heals. This can be especially useful for children in whom suture removal can be difficult, for lacerations under casts, or if a patient will not be able to follow up due to travel.

NONABSORBABLE SUTURE MATERIALS

Nonabsorbable sutures are not degraded by the body and must be removed. They maintain their tensile strength for longer than 60 days. They are composed of monofilament or polyfilament strands of organic, synthetic, or metal fibers (**Table 116-2**). Nonabsorbable sutures generally have greater tensile strength and lower tissue reactivity than absorbable sutures. They are used in a variety of applications including skin closure. Nonabsorbable sutures can be used within a body cavity and subcutaneously, where they will eventually become encapsulated in connective tissue.

Nonabsorbable sutures can be classified as organic, synthetic, and wire. Organic sutures include those made of cotton or silk. Cotton is the oldest of the nonabsorbable sutures. It is not discussed here as cotton sutures are no longer used in general medical practice. Silk is a polyfilament suture that has limited use in the practice of Emergency Medicine. There are several advantages to silk suture

TABLE 116-2 Nonabsorbable Suture Materials

Suture type	Source	Tensile strength	Tissue reaction	Knot security	Absorption
Silk (braided)	Organic protein	Gradual loss by progressive degradation	High	Good	Gradual encapsulation by connective tissue
Ethilon	Polyamide (nylon)	Progressive hydrolysis may result in gradual loss of tensile strength	Minimal	Fair	Gradual encapsulation by connective tissue
Nurolon	Polyamide (nylon)	Progressive hydrolysis may result in gradual loss of tensile strength	Minimal	Fair	Gradual encapsulation by connective tissue
Prolene	Polyamide (nylon)	Not subject to degradation	Minimal	Poor	Nonabsorbable
Mersilene	Polyester	No significant change occurs	Minimal	Good	Gradual encapsulation by connective tissue
Ethibond	Coated polyester	No significant change occurs	Minimal	Good	Gradual encapsulation by connective tissue
V-Loc PBT	Polybutanester	Indefinite, high	Minimal	N/A	Nonabsorbable
Tissue adhesive	Synthetic chemicals	Low	Minimal	N/A	Nonabsorbable, falls off
Stainless steel	Stainless steel	Indefinite, high	Minimal	Good	Nonabsorbable
Staples	Inert metals	Indefinite, high	Minimal	N/A	Nonabsorbable

material. Its pliability makes it very easy to handle. It holds knots better than other types of suture. However, as with all natural and/or polyfilament sutures, it has a greater tendency to cause wound infections. The polyfilament braids can provide a place for bacteria to lodge. Silk suture may actually protect the bacteria from attack by the body's defenses if the wound becomes infected. The primary use of silk sutures in the Emergency Department is for the repair of lip, oral cavity, and tongue lacerations.

Synthetic nonabsorbable sutures are available in monofilament and polyfilament forms. Commonly used synthetic sutures include nylon, polypropylene, polybutester, and Dacron. Nylon, polypropylene, and polybutester are monofilament synthetic sutures. Dacron is a polyfilament synthetic suture. The synthetic nonabsorbable sutures have several advantages over the natural nonabsorbable sutures. They are less reactive in tissues, generally stronger than the natural sutures, and retain their tensile strength over many years.

Nylon (e.g., Ethilon and Dermalon) is the most common nonabsorbable suture used in the Emergency Department. It is a monofilament suture, is inert, and does not tend to harbor bacteria. It is primarily used for skin closure. Nylon has good tensile strength and minimal tissue reactivity. However, nylon is difficult to handle and difficult to tie. It requires more knots to achieve good knot security than other types of suture. This is primarily due to the tendency of the suture to return to its packaged shape. This tendency is also known as "memory." Because the knot can unravel or slip, it is important to place at least four or five knots when using nylon suture.

Polypropylene and polybutester are less commonly used synthetic nonabsorbable sutures. Polypropylene (e.g., Prolene) is stronger but more difficult to work with than nylon because it has greater memory. Polybutester (e.g., Novafil) is a newer suture in this category. It is stronger than the other monofilaments and does not have significant memory. Therefore, it is easier to work with than the other monofilament synthetic sutures.

EQUIPMENT

- Needle drivers, 4.5 and 6.0 inch
- Skin hooks
- Scalpel blades (#10, #11, #15)
- Scalpel handles
- Iris scissors, straight 4 inch and curved 4 inch
- Suture scissors, 6 inch
- Forceps, toothed Adson

- Metzenbaum scissors, curved 6 inch
- Hemostats, straight 6 inch, and curved mosquitoes
- Suture material
- Skin closure tapes
- Benzoin solution, swabs or spray
- Gum mastic (e.g., Mastisol)
- Tissue adhesive
- Tissue adhesive forceps
- Skin stapler
- Staple remover
- Gauze, 4×4 squares

Much of the above equipment can be purchased in single-use, sterile, and disposable suture kits from several commercial manufacturers (**Figure 116-1A**). These kits tend to be expensive and occasionally have a limited amount of equipment. Many hospitals package and sterilize their own wound repair kits (**Figure 116-1B**). This decreases the cost, as the equipment can be repeatedly sterilized and reused. It also allows the kits to contain a wide variety of instruments for multiple situations (e.g., minor laceration, large laceration, and plastics closure).

Needle drivers come in a variety of sizes. A 4.5 inch needle driver can be used comfortably with most types of needles. A 6 inch needle driver may be required if large needles are used to close a wound. Hold the needle driver with the fingertips to provide greater flexibility. The fingers can also be placed through the finger holes, but this is not as efficient when closing a wound. Grasp the needle one-third of the way from the swag (distal) end with the tip of the needle driver.

The skin must be grasped and manipulated during wound repair to allow for proper suture placement. Forceps are most commonly used to grasp and manipulate the skin. **Smooth (i.e., nontoothed) forceps should never be used to grasp skin.** They require the application of a large amount of force to grasp the tissue. This can crush tissue very easily. An Adson forceps is the forceps of choice. It has fine teeth that grasp tissue securely with minimal force.

A skin hook is a sharp, pointed instrument that is inserted into the wound edge and grasps the tissue from the undersurface. It produces a small puncture wound in the subcutaneous tissues and does not penetrate the skin surface. Skin hooks are preferable to forceps, as they do not crush tissues. A skin hook is awkward to use at first. With proper instruction and experience, the Emergency Physician will most certainly prefer a skin hook to forceps.

A

B

FIGURE 116-1. The equipment required for basic wound closure techniques. **A.** The contents of a disposable and commercially available wound closure kit. **B.** A hospital packaged kit with reusable instruments.

Several types of scissors are required for proper wound closure. Iris scissors have sharp, delicate tips for making precise cuts in tissue. They should not be used to cut suture material, as this rapidly dulls and nicks the blades. Suture scissors have one blunt tip and one pointed tip. Both blades of the suture scissors are sharp. Suture scissors are used to cut adhesive tape, gauze, rubber drains, and suture material. Metzenbaum scissors should be used to debride heavy tissue, bluntly dissect tissue, and undermine tissue.

Hemostats are used to clamp small vessels that are bleeding, to explore a wound, and to grasp fascia. Hemostats are available in a variety of sizes and styles. A straight 6 inch hemostat is used for most purposes during wound repair. A curved 5 inch mosquito hemostat can be used for small wounds or delicate tissues. **Do not use a hemostat to grasp or drive the suture needle.** The suture needle can bend, rotate, and break as it enters tissue if driven by a hemostat.

Three different scalpel blades should be available when a wound is being repaired. A #11 blade is used to make stab incisions. It is often used for the incision and drainage of abscesses, cricothyroidotomies, and the removal of small or tight sutures. A #10 blade is used to make straight cuts in the skin and debride wound edges. It is rarely used in laceration repair. A #15 blade is small and curved to allow precise incisions. It is used for excising foreign bodies and wound debridement.

SUTURE TECHNIQUES

Proper wound closure requires an understanding of certain basic principles. **The needle should enter and exit the skin at a 90° angle and perpendicular to the wound edges.** By doing so, when the suture loop is closed, the wound edges will be everted. **Sutures should be placed as close to the wound edge as possible (i.e., 2 to 3 mm) in order to avoid excessive tension on the wound.** More force will be required to close the wound if the sutures are placed too far from the wound edge. Edema develops in a wound in the first 48 hours after closure. Sutures placed too far from the wound edge can result in large scars when the edema subsides.

The layers of the wound should be matched evenly and each layer should be closed separately. If a wound involves the deeper layers of skin, fascia should be matched to fascia, dermis should be matched to dermis, and epidermis should be matched to epidermis. **The proper matching of layers avoids an uneven closure, helps to prevent an unnecessarily large scar, and eliminates any dead space.**

The epidermal edges of the wound must be everted to allow for proper healing. Scars contract with time. They will flatten and heal with a better cosmetic result if the wound edge is everted and slightly elevated. If the wound edges are not everted they will contract into a “pit” below the plane of the skin, will be more noticeable, and the final result will be less appealing cosmetically.

Handle the tissues gently and do not squeeze or twist them too tightly with the instruments. This helps to avoid strangulation,

which can result in tissue necrosis. **The sutures should be placed carefully and with the proper amount of tension to help promote healing.** Sutures should be snug. Attempts should be made to avoid excessive tension on the wound edges in order to prevent wound dehiscence. The use of the smallest suture size necessary to approximate the wound edges will reduce tissue damage and minimize scarring. **Table 116-3** lists the appropriate suture types and sizes for each body region.

If there will be a temporary delay in the closure of a laceration because of other injuries that may be life-threatening or of greater importance, cover the wound with a saline-soaked gauze in order to keep the tissues from drying.

PRINCIPLE OF HALVING

Large wounds gape open and are difficult to approximate. Closure of the deeper layers will often bring the skin edges into apposition. If not, the principle of halving may be used to approximate the wound (**Figure 116-2**). Identify the midpoint of the laceration. Place the first suture at the midpoint (**Figure 116-2A**). This stitch is known as the central suture. The next sutures are placed in halves on each side of the central suture (**Figures 116-2B and 116-2C**). Continue the process by placing sutures halfway between previous sutures until the wound is approximated. This results in even closure of the wound edge. This principle can be used for closure of both the deep layers and the skin.

TWO-HANDED SQUARE KNOT

This is the easiest and most reliable method of tying most suture materials. It involves the classic “right-over-left and left-over-right” tie (**Figure 116-3**). The incorrect “right-over-left and right-over-left” is a granny knot which will slip if it is tied in this manner. This square knot is quick and simple to perform. However, it does take significant practice to master this technique.

Place a suture through the skin on both sides of the laceration (**Figure 116-3A**). Pull the suture through the wound until half is on each side of the laceration. Grasp the right half of the suture with the right thumb and index finger (**Figure 116-3A**). Grasp the left half of the suture with the left third through fifth fingers and the suture draped over the thumb (**Figure 116-3A**). Cross the right hand toward the left hand (**Figure 116-3B**). Continue to move the right hand until the suture is between the left thumb and index finger (**Figure 116-3C**). Close the left thumb and index finger to entrap the right half of the suture in the pads of the fingers (**Figure 116-3D**). Pull the right hand down and to the left so that the two halves of the suture form an “X” over the left thumb (**Figure 116-3E**). Flex the left wrist to slide the “X” off the left thumb and onto the left index finger (**Figure 116-3F**). Lift the left thumb backward and upward so that the “X” overlies the tip of the left index finger (**Figure 116-3G**). Reapply the left thumb over the left index finger to entrap the “X” (**Figure 116-3H**). Extend the left wrist

TABLE 116-3 Typical Suture Choices for Each Body Site

Anatomic site	Deep-layer suture size	Deep-layer suture material	Skin-layer suture size	Skin-layer closure material
Scalp	2-0, 3-0, or 4-0	Absorbable	4-0 or 5-0	Nylon, polypropylene, or staples
Eyelid	5-0, 6-0, or 7-0	Absorbable	6-0 or 7-0	Nylon or polypropylene
Face	4-0 or 5-0	Absorbable	5-0 or 6-0	Nylon or polypropylene
Neck	4-0 or 5-0	Absorbable	4-0 or 5-0	Nylon or polypropylene
Trunk	3-0 or 4-0	Absorbable	3-0 or 4-0	Nylon, polypropylene, or staples
Extremities	3-0 or 4-0	Absorbable	3-0, 4-0, or 5-0	Nylon, polypropylene, or staples
Hands and feet	Not advisable	Not applicable	4-0 or 5-0	Nylon or polypropylene
Sole of foot	3-0 or 4-0	Absorbable	3-0 or 4-0	Nylon or polypropylene

FIGURE 116-2. The principle of halving. **A.** The first suture is placed in the middle of the laceration. **B.** The second suture is placed halfway between the first suture and the upper end of the laceration. **C.** The third suture is placed halfway between the first suture and the lower end of the laceration.

to push the left thumb and the “X” through the loop (**Figure 116-3I**). Release the suture held with the right hand (**Figure 116-3J**). Re-grasp the suture with the right hand after it passes through the loop (**Figure 116-3K**). Pull the suture completely through the loop with the right hand. Simultaneously move the left hand toward the left and move the right hand toward the right (**Figure 116-3L**). Cross the hands so that the left hand goes toward the right side and the right hand goes toward the left side (**Figure 116-3M**). Continue to pull both sides of the suture until the knot lies flat and the skin edges are apposed (**Figure 116-3M**). The first half of the knot is now complete.

Make the second half of the knot to complete the square knot. Raise both hands upward and uncross them until an “X” is formed over the left index finger (**Figure 116-3N**). Close the left thumb

FIGURE 116-3. The two-handed square knot. The two halves of the suture are different colors to make viewing easier.

FIGURE 116-3. (Continued)

and index finger to entrap the suture being held with the right hand (**Figure 116-3O**). Extend the left wrist to push the left thumb through the loop (**Figure 116-3P**). Lift the left index finger upward (**Figure 116-3Q**). Move the right hand away from you until the suture it holds drapes over the left thumb (**Figure 116-3R**). Reapply the left index finger onto the thumb to entrap the suture held with the right hand (**Figure 116-3S**). Release the suture held with the right hand (**Figure 116-3T**). Flex the left wrist to push the left index finger and suture through the loop (**Figure 116-3U**). Re-grasp the free suture with the right hand after it passes through the loop (**Figure 116-3V**). Move the right hand upward and to the right to complete the second half of the knot overlying the left index finger (**Figure 116-3W**). Simultaneously move the left hand toward the left and move the right hand toward the right (**Figure 116-3X**). Continue to pull both halves of the suture until both halves of the knot come into contact (**Figure 116-3Y**). Pull both halves of the suture to secure the knot. The square knot is now complete. Continue the process to add additional knots onto the suture. Cut off excess suture on both sides of the knots.

SURGEON'S KNOT

The physician may choose to use a surgeon's knot instead of a square knot (**Figure 116-4**). The square knot has one loop in the first throw

FIGURE 116-4. The square knot (**A**) versus the surgeon's knot (**B**). The first throw of the square knot has one loop (**A**), while that of the surgeon's knot has two loops (**B**). The second throw of both knots are a simple loop.

and one loop in the second throw (**Figure 116-4A**). The surgeon's knot has two loops in the first throw and one loop in the second throw (**Figure 116-4B**). The only difference between these two knots is the two loops in the first throw. The second throw and subsequent knots are exactly the same for both knots. The advantage of the surgeon's knot is that the two loops are more secure and stay in place while the second throw is being tied. Thus, the laceration tends to stay closed while the second throw is being formed. The

choice to use either knot is dependent on the experience and the training of the physician.

INSTRUMENT TIE

The instrument tie is the most efficient method to complete a simple interrupted suture (**Figure 116-5**). It is the tie that is most commonly used in the Emergency Department. An instrument tie

FIGURE 116-5. The instrument tie.

FIGURE 116-5. (Continued)

is often quicker, requires less dexterity, and is easier to perform than the two-handed method. It may be used with the square knot or the surgeon's knot.

Place a suture through the skin on both sides of the laceration (**Figure 116-5A**). Carefully grasp the needle in its midportion and pull it through the laceration (**Figure 116-5B**). Continue to pull the needle until approximately 1 to 2 cm of suture on the tail end remains outside the laceration (**Figure 116-5C**). A large amount of suture will be wasted if the tail is left too long, as it will be later cut off and discarded. On first learning the instrument tie, it may be best to leave a tail of 3 to 4 cm until one is proficient with this technique.

Place the needle driver over the laceration but not touching it (**Figure 116-5C**). Loosely loop the needle end of the suture over (**Figure 116-5D**) and around (**Figure 116-5E**) the needle driver. Loosely loop the needle end of the suture over and around the needle driver a second time (**Figures 116-5F and 116-5G**). This will eventually result in the first half of a surgeon's knot. Looping the suture once around the needle driver will result in a simple square knot. Move the tip of the needle driver toward the tail of the suture without letting the loops fall off the needle driver (**Figure 116-5H**).

Grasp the tail of the suture with the needle driver (**Figure 116-5I**). Pull the tail of the suture through the loop (**Figure 116-5J**). Pull the tail completely through the loops (**Figure 116-5K**). Simultaneously move the left hand toward the right and the right hand/needle driver toward the left (**Figure 116-5L**). Continue to pull both sides of the suture until the hands are opposite each other, the knot lies flat, and the skin edges are apposed (**Figure 116-5M**). The first half of the knot is now complete.

Make the second half of the knot. Continue to hold the needle and release the tail of the suture from the needle driver (**Figure 116-5N**). Place the needle driver over the laceration but not touching it (**Figure 116-5N**). Loosely loop the needle end of the suture over (**Figure 116-5O**) and around (**Figure 116-5P**) the needle driver. Move the tip of the needle driver toward the tail of the suture without letting the loop fall off the needle driver (**Figure 116-5Q**). Grasp the tail of the suture with the needle driver (**Figure 116-5R**). Pull the tail of the suture completely through the loop (**Figure 116-5S**). Simultaneously move the left hand toward the left and the right hand/needle driver toward the right (**Figure 116-5T**). Continue to pull both sides of the suture until both halves of the knot come into contact. Pull both sides of the suture to secure the knot. The knot is

FIGURE 116-6. The simple interrupted stitch.

now complete. Continue this process three or four more times, each in alternative directions, to place additional knots. Cut off the excess suture on both sides of the knots.

SIMPLE INTERRUPTED STITCH

The simple interrupted stitch is the most commonly used suture technique and is useful in many situations (**Figure 116-6**). One major advantage is that each stitch is placed independent of the others. Therefore, tension on each stitch can be adjusted separately. Additionally, the entire repair is not compromised if one suture should happen to come out. The other sutures will remain in place to help assure proper wound healing. **The needle must enter and exit the skin at a 90° angle to help evert the wound edges. Take equal volumes of skin from each side of the area being sutured. Drive the needle equidistantly into and out of the wound edges and incorporate the base of the wound.**

Insert the needle at a 90° angle to the skin (**Figure 116-6A**). Drive the needle through the tissue until the tip exits the skin (**Figure 116-6B**). Grasp the needle behind the tip and pull it through the wound (**Figure 116-6C**). **The suture should enter and exit the skin equidistant from the wound edges (Figure 116-6D).** If it does not, pull the suture out and repeat the stitch so that it is equidistant from the wound edges. Make a loop in the suture with the two-handed tie or the instrument tie. Pull the suture to appose the wound edges and cinch down the knot (**Figure 116-6E**). The tissue at the base of the wound will come into apposition before the tissue at the skin surface and thus evert the wound edge. Complete the knot to one side of the laceration (**Figure 116-6F**). Just prior to cinching the second throw onto the first, pull the ends so that the knot is not directly over the wound and the edges of the wound remain in apposition. Apply additional sutures equidistant from each other until the wound is closed (**Figure 116-6G**).

OPEN-LOOP SIMPLE INTERRUPTED STITCH

The open-loop simple interrupted stitch is a variation of the simple interrupted stitch (**Figure 116-7**). The same basic technique is used except that the knot is tied differently. The tie involves laying down the first knot with an instrument tie. However, the second

knot placed on the suture is not pulled all the way down. Pull the second knot only until it is just above the first knot (**Figure 116-7A**). In other words, the second knot is loosely tied, leaving a loop between the first and second knots. Place a third knot as a single knot square to the second knot (**Figure 116-7B**). Cinch the third knot tightly to the second knot. This “locks” the third knot onto the second knot.

This knot is indicated when there is the possibility of edema forming at the suture site. If edema forms, the first knot will have room to open as it slides toward the second knot. This stitch avoids excessive tension on the wound and prevents the suture from cutting into the skin. This stitch facilitates suture removal when numerous small stitches are placed next to a wound edge. Cutting the open loop

FIGURE 116-7. The open-loop simple interrupted stitch.

unravels the knot and allows for easy removal of the suture. This stitch should not be used in areas where the skin is thin or if there is little subcutaneous tissue (e.g., dorsal hand and foot). In these areas, the wound edges often become unopposed while the knot is being secured.

INTERLOCKING SLIP KNOT

This technique can be used in patients who will be traveling, camping, or otherwise away from their primary source of medical care (**Figure 116-8**). The patient can easily remove the sutures without having to find an unfamiliar or foreign health care provider for routine suture removal. The interlocking slip knot can be removed by hand without the use of a scissors or a scalpel. This can be useful for suture removal in pediatric patients, who may find it hard to sit still for suture removal.

Place a suture through the skin on both sides of the laceration (**Figure 116-8A**). Loop the tail end of the suture around the tip of the needle driver (**Figure 116-8A**). Grasp the needle end of the suture with the needle driver (**Figure 116-8B**). Pull the needle end of the suture through the loop while simultaneously pulling on the tail end of the suture with a second needle driver or your hand (**Figure 116-8C**). Continue to pull both suture halves in opposite directions until a knot is formed against the skin and the wound edges are apposed (**Figure 116-8D**).

Release the needle driver holding the now formed loop. Insert the needle driver through the loop and grasp the tail end of the suture (**Figure 116-8E**). Grasp the needle end of the suture with the second needle driver or your hand (**Figure 116-8E**). Pull the needle drivers in opposite directions to lock and secure the knot (**Figure 116-8F**). The knot is now complete (**Figure 116-8G**). To remove the stitch, pull the free end of the suture to unlock the knot. Continue to pull the suture until it is free from the skin. This stitch can easily become loose or open before the wound is healed. Thus, it is recommended to cover the wound and sutures with skin closure tape (e.g., Steri-Strips).

CONTINUOUS OVER-AND-OVER STITCH (SIMPLE RUNNING STITCH)

Continuous (simple running) sutures minimize the time required for laceration repair. Stitches can be placed very quickly, since each individual stitch does not have to be tied. This stitch provides strength and applies equal tension on all sutures in the repair. This stitch can be used to achieve hemostasis. The wound must be long and straight. Simple running stitches can effectively be used in partial-thickness lacerations and wounds under minimal tension.

However, there are several disadvantages to this stitch. It can be associated with significant epithelialization of the suture track. This is especially true if the suture is not removed early and remains for a prolonged period of time. Inclusion cysts may form within a few weeks after removal of the sutures. **Simple running stitches should not be used on any wound under tension.** If one suture breaks, the entire wound may open. **This stitch should not be used when closing a wound where there is a risk of subsequent hematoma formation.** Hematoma formation would require the removal of all of the sutures in order to drain the hematoma. Although this suture is not commonly used in the Emergency Department, it can be very helpful for closing bleeding scalp wounds, as the injury will be covered with hair and cosmesis is a secondary concern.

Place the initial stitch as a simple interrupted stitch (**Figures 116-9A**). Do not cut the suture after the knots are securely tied. Place a second stitch 3 to 5 mm from the first stitch as if placing another simple interrupted stitch (**Figures 116-9B and 116-9C**). Place a third stitch 3 to 5 mm from the second stitch (**Figures 116-9D and 116-9E**). Continue to place additional stitches until the end of the laceration is reached. **Use care to ensure that the sutures are all lined up with each other and equidistant from the laceration.** Do not pull the last throw taut against the skin (**Figure 116-9F**). The loop will act as the tail end of the suture for knot tying. Loop the needle end of the suture twice around the tip of the needle driver (**Figure 116-9G**). Grasp the last throw with the tips of the needle driver (**Figure 116-9G**). Pull the last throw through the loops until the knot is against the skin (**Figure 116-9H**). Perform three to five

FIGURE 116-8. The interlocking slip knot. The two halves of the suture are different colors to make viewing easier.

FIGURE 116-9. The continuous over-and-over or simple running stitch.

more instrument ties to secure the knot. Cut off the excess suture (**Figure 116-9I**).

CONTINUOUS SINGLE-LOCKED STITCH (RUNNING-LOCKED CLOSURE)

This stitch may promote less epithelialization of the suture track than the continuous over-and-over or simple running stitch. It maintains the advantages of a continuous suture. This variation of the simple running closure locks each stitch after it is placed (**Figure 116-10**). It provides a secure apposition of the wound edges while each subsequent stitch is placed. The main disadvantage of this stitch is the time it takes compared to a continuous over-and-over or simple running stitch.

Place the initial stitch as a simple interrupted stitch (**Figure 116-10A**). Do not cut the suture after the knots are securely tied. Loop the tail end of the suture over the nondominant fifth finger (**Figure 116-10B**). Apply slight tension on the tail end of the suture while placing the second stitch (**Figures 116-10C and 116-D**). As the needle exits the

skin, move the nondominant hand to bring the suture loop down and over the needle (**Figure 116-10E**). Grasp the needle with the needle driver. Simultaneously pull the needle and suture through the laceration while releasing the loop from the fifth finger (**Figure 116-10F**). Repeat this procedure until the laceration is closed (**Figure 116-10G**). **Do not pull the last throw taut against the skin.** The loop will act as the tail end of the suture for knot tying. Loop the needle end of the suture twice around the tip of the needle driver (**Figure 116-10H**). Grasp the last throw with the tips of the needle driver. Pull the last throw through the loops until the knot is against the skin (**Figure 116-10I**). Perform three to five more instrument ties to secure the knot. Cut off the excess suture (**Figure 116-10J**).

VERTICAL MATTRESS STITCH

The vertical mattress stitch is a double stitch that provides for excellent wound eversion and hemostasis (**Figure 116-11**). It optimizes wound closure of lacerations under tension. This stitch is useful in areas where the skin is very lax, such as the elbow and

FIGURE 116-10. The continuous single-locked or running-locked stitch.

FIGURE 116-11. The vertical mattress stitch.

FIGURE 116-12. The “shortcut” vertical mattress stitch. An alternative method to place the vertical mattress stitch.

the dorsum of the hand. This stitch provides for both superficial as well as deep closure of lacerations. **This stitch is contraindicated in lacerations involving the volar aspect of the hands and feet or the face, as it requires the blind placement of a deep suture.** The main disadvantage of the vertical mattress closure is the time it takes to place it.

Place the first throw much like a simple interrupted stitch with a few noted differences. The needle should enter and exit the skin 1.0 to 1.5 cm from the wound edge. The needle should traverse the base of the wound and grasp a large amount of tissue (**Figures 116-11A and 116-11B**). Reverse the needle. The second throw should enter and exit the skin approximately 2 to 3 mm from the wound edge (**Figures 116-11C and 116-11D**). **The first and second throws must be directly over each other and parallel.** Tie the suture to approximate the wound edges (**Figures 116-11E**). The first throw will close the wound base and relieve the tension at the skin surface. The second throw approximates and everts the skin edges.

The newer version of the classic vertical mattress is referred to as the “shorthand” vertical mattress stitch (**Figure 116-12**). It provides wound eversion in half the time as the traditional method. Place the first throw close to the lacerated wound edge to approximate the skin edges (**Figures 116-12A and 116-12B**). Grasp and pull the suture to elevate the wound edges (**Figure 116-12C**). This allows the needle to more easily take a large bite of tissue on the second throw. Place the second throw 1.0 to 1.5 cm from the wound edge (**Figures 116-12C and 116-12D**). Release the suture. Tie the suture to approximate the wound edges and evert the skin surface (**Figure 116-12E**). The final product looks exactly the same as the traditional vertical mattress suture (**Figure 116-12F**).

LOCKED VERTICAL MATTRESS STITCH

The locked vertical mattress stitch is useful in areas that are widely separated, where deep sutures must be avoided, and in areas that

FIGURE 116-13. The locked vertical mattress stitch.

keep bleeding such as the scalp (Figure 116-13). This stitch helps to reduce the amount of tension needed to close a wound and provide hemostasis. It helps to avoid the pain and scarring that can result if too much tension is applied to a laceration. It does not put an excessive amount of tension on the deep throw, as does the vertical mattress stitch.

This is a modification of the vertical mattress stitch (Figures 116-11 and 116-12). Place the first two throws as if placing a vertical mattress stitch (Figure 116-13A). Leave the suture lax with a loop above the wound surface. Pass the needle end of the suture through the open loop (Figure 116-13B). This step will form the locked portion of the stitch. Pull the needle end of the suture taut to appose the wound edges (Figure 116-13C). Tie and secure the suture ends in the standard manner.

HORIZONTAL MATTRESS STITCH

The horizontal mattress stitch is placed along the axis of the wound and helps to eliminate tension on the wound (Figure 116-14). It is a good closure technique for wounds with relatively poor circulation to the wound edges because, theoretically, no suture is placed through the wound edges. This helps to avoid tension on the wound edges from the suture and subsequent local necrosis. This stitch is placed more rapidly than the vertical mattress stitch. It requires fewer stitches to close a wound with horizontal rather than vertical mattress stitches. The throws are side by side rather than on top of each other, as with the vertical mattress, and each stitch closes more tissue. This closure may be used superficially on the volar surfaces of the hands and fingers, as these delicate skin areas may swell and be cut by simple interrupted sutures. The main disadvantage of the horizontal mattress stitch is that it takes more experience to properly place this stitch to achieve wound eversion than with the vertical mattress stitch.

Place the first throw much like a simple interrupted stitch with a few noted differences. The needle should enter and exit the skin 0.5 to 1.0 cm from the wound edge. The needle should traverse the base of the wound (Figures 116-14A and 116-14B). Reverse the needle and make a second throw 0.5 cm from the first (Figure 116-14C). **The needle must enter and exit the skin and the wound edges**

so that the first and second throws are parallel to each other (Figures 116-14C and 116-14D). Pull the free ends of the suture taut to appose and evert the wound edges (Figures 116-14E and 116-14F). Tie and secure the suture in the standard manner.

HALF-BURIED HORIZONTAL MATTRESS STITCH

This is the stitch of choice to close complex wounds with multiple flaps in a single-layer closure. This stitch is ideal to close stellate, Y-shaped, V-shaped, and T-shaped lacerations. The half-buried horizontal mattress stitch allows a tissue flap to be reapproximated without tension on the edges of the flap. The vascular supply to a flap is derived from its base. The flaps sometimes have a limited or poor vascular supply. This stitch may be used to approximate a flap-like laceration in which the corner has limited vascularity and/or viability.

The key to this stitch is that the needle and suture pass through the dermis of the flap and not the epidermis (Figure 116-15). Begin by placing the first stitch percutaneously through the skin adjacent to the tip of the flap (Figure 116-15A). Advance the needle through the dermal layer of the flap, through the dermal layer of the skin adjacent to the tip of the flap, and out the skin adjacent to the tip of the flap opposite to where the stitch began (Figure 116-15A). **The needle must traverse the dermis of the flap and adjacent tissue at the same level of the dermis to properly approximate the wound edges.** Gently pull on the free ends of the suture to approximate the flap against the adjacent skin edges. Tie and secure the suture in the usual manner. Secure the edges of the flap with half-buried horizontal mattress stitches (Figure 116-15A), simple interrupted stitches, vertical mattress stitches, or horizontal mattress stitches.

Stellate lacerations are often seen in the Emergency Department. They occur due to bursting of the skin from crush injuries. These lacerations are often encountered on the extremities, forehead, and scalp. Begin by inserting the needle through the skin of the largest flap (Figure 116-15B). Advance the needle so that its tip exits the dermis. Continue to advance the needle through the dermis of each flap. The half-buried horizontal mattress stitch should encompass the tips of all the flaps (Figure 116-15B). The remainder of the procedure is as described above.

FIGURE 116-14. The horizontal mattress stitch.

FIGURE 116-15. The half-buried horizontal mattress stitch is used to approximate a star-shaped (stellate) laceration (A) and a Y-shaped laceration (B).

CONTINUOUS (RUNNING) HORIZONTAL MATTRESS STITCH

The running horizontal mattress stitch is indicated in areas of the body where there is loose skin that tends to overlap or invert, such as the skin of the upper eyelids or the dorsum of the hand. This stitch can also be used as the surface closure in a multiple-layer closure if there is a tendency for wound inversion. Like the traditional horizontal mattress stitch, it provides good apposition and can be placed rapidly. The running horizontal mattress stitch is contraindicated in wounds under tension if the goal of wound closure is optimal cosmesis.

This stitch begins with a simple interrupted stitch at one end of a laceration (Figure 116-16). The needle is then run along the length of the wound while placing horizontal mattress stitches. The difference between this and the standard horizontal mattress stitch is that the suture is not tied and cut after each individual stitch. Rather, the stitch is continued (running) the length of the laceration. At the end of the laceration, the stitch is tied and secured in the same way as the continuous over-and-over or simple running stitch (Figure 116-9).

CONTINUOUS SUBCUTICULAR STITCH

This closure is ideal for lacerations of the face and neck. It provides excellent cosmesis, leaves no suture marks on the skin, and causes minimal scarring. It requires more time and skill to place than other types of stitches. It may be performed for the temporary pull-out (Figure 116-17) or permanent placement (Figure 116-18) of subcutaneous sutures. Polypropylene or nylon sutures should be used for the pull-out stitch. Polypropylene is preferred for the pull-out stitch as it is stiffer, stronger, and easier to remove than nylon. The use of polypropylene or polyglactin 910 permanently placed as the subcuticular stitch has been shown to be cosmetically equal to polypropylene removed in 14 days.¹³

The use of this stitch is limited to lacerations that are clean and straight, have sharp edges, and are less than 6 cm in length. It may be extremely difficult to remove the suture material for the pull-out technique if the laceration is greater than 6 cm in length. The laceration can be longer if the permanent placement of absorbable (e.g., Vicryl) sutures is being done. The dermis and subcutaneous

FIGURE 116-16. The continuous or running horizontal mattress stitch.

FIGURE 116-17. The continuous subcuticular pull-out stitch.

tissue must be apposed before proceeding with this stitch. If necessary, apply buried absorbable sutures to appose the dermis before applying this stitch. **The superficial wound surface must be tension-free, as this stitch is for cosmesis and not strength.** The wound may require undermining to release the tension from the wound edges. Refer to Chapter 114 for the details regarding wound undermining.

The pull-out technique allows the subcuticular stitch to be removed after the laceration heals (Figure 116-17). The subcuticular suture should enter the intact skin 3 to 4 mm from one end of the laceration and burrow through the dermal-epidermal junction to emerge through the skin at the other end of the laceration (Figure 116-17A). The suture will continuously pass through the subcuticular layer on alternate sides of the laceration. **The point of entry of each stitch should be directly across from or slightly behind the exit point of the previous stitch. It is very important to keep the needle at the same level of depth throughout the wound.**

FIGURE 116-18. The continuous subcuticular permanent stitch.

The tension on the suture should be adjusted to ensure that there is **no puckering of the skin**. Tape the free suture at both ends of the laceration to the skin (**Figure 116-17B**). Place wound tape (e.g., Steri-Strips) across the laceration to help maintain the apposition of the epidermis. This stitch is easily removed. Remove the wound tape and slowly pull one end of the suture with a needle driver.

As an alternative, the continuous stitch may be placed using absorbable suture material to provide longer-lasting strength to the wound (**Figure 116-18**). Suture material of choice includes Dexon, PDS, or Vicryl. The same indications, preparation, and stitch are used as with the pullout technique. The only difference is in the starting and ending stitch. Place the first stitch into the dermis, just inside the laceration edge, as a buried knot (**Figures 116-18A, 116-18B, and 116-18C**). Place the continuous suture until the opposite end of the laceration is reached (**Figure 116-18D**). The final throw should be left lax with a trailing loop of suture (**Figure 116-18E**). The loop should be used as the “tail end” to perform an instrument tie (**Figure 116-18F**). Tie three or four knots in the suture. Lift the free ends of the suture and cut them just above the knot. Apply wound tape across the laceration to help maintain the apposition of the wound.

BURIED (SUBCUTANEOUS) KNOT STITCH

This stitch helps to decrease potential dead space underneath a laceration, decreases the tension on the skin surface, and gives tensile support for up to 4 to 6 weeks while the wound is still weak. The loop is constructed so that the knot lies at the bottom of the wound base (**Figure 116-19**). This helps to keep the skin surface smooth and flat. The buried knot stitch is most useful in closing subcutaneous tissue just under the skin surface. It is preferable to use monofilament absorbable suture for a buried stitch.⁵

This stitch requires practice to master. Insert the needle into one side of the base of the wound (**Figure 116-19A**). Drive the needle from deep to superficial and exiting at the dermal-epidermal junction (**Figure 116-19A**). Insert the needle through the dermal-epidermal junction on the opposite side of the wound and drive it through the base of the wound (**Figure 116-19B**). **The suture should exit the base of the wound across from and level with the entrance site of the first throw.** Pull both free ends of the suture up and out through the laceration (**Figure 116-19C**). Tie a knot in the suture (**Figure 116-19D**). Pull both free ends of the suture to lower the knot to the base of the wound and appose the tissue (**Figure 116-19E**). Tie two additional knots to secure the suture. Cut off any excess suture.

FIGURE 116-19. The buried (subcutaneous) knot stitch.

REINFORCING (RETENTION) SUTURES FOR WOUNDS UNDER TENSION

Reinforcing or retention sutures are particularly useful for wounds in which the edges are widely separated or where the skin is too atrophic to approximate without the suture cutting through the skin. The reinforcing sutures help to decrease the tension on the wound by providing more support for the wound edges. Reinforcing sutures can be placed using sterile buttons, Perchick buttons (Angiodynamics, Latham, NY), or rubber tubing (**Figure 116-20**). Heavy sizes of nonabsorbable suture materials are used for reinforcing sutures. This is not for strength but to avoid the finer suture from cutting through the tissue.

Ideally, a double-swaged (needle) suture should be used to place suture from the inside of the wound toward the outside skin to avoid pulling potentially contaminated epithelial cells through the wound. The stitch is placed like the horizontal mattress stitch and sterile buttons or rubber tubing is used to achieve approximation to a point where the wound edges can be closed without significant tension (**Figures 116-20B and 116-20C**). **Do not attempt to appose the wound edges when using retention sutures.** Appose the remaining skin edges with simple interrupted, vertical mattress, or horizontal mattress stitches. The reinforcing sutures should remain in place after the skin sutures are removed. The reinforcing sutures should be removed after the wound has healed and gained significant tensile strength.

SUTURE REMOVAL TECHNIQUES

Remove sutures as soon as possible to avoid the possibility of infection and prevent the formation of suture marks. However, if they are removed too early, wound dehiscence may occur. Simple interrupted sutures should be cut at the end away from the knot and then pulled out (**Figure 116-21A**). This helps to prevent the outer contaminated portion of the suture from passing back through the wound. In order to remove a running simple or running-locked stitch, grasp the knot at the end of the closure and cut each loop (**Figures 116-21B and 116-21C**). Pull out each individual suture piece. Vertical and horizontal mattress sutures can be removed in much the same way as the simple interrupted stitch (**Figures 116-21D and 116-21E**).

Patients often take out their own sutures, much to the dismay of Emergency Physicians. This is understandable when you think of the time it takes to go somewhere just to get the sutures removed in 2 minutes. An interesting study looked at sending the patient home with a suture removal kit and suture removal instructions.¹⁴ Most patients were willing to remove their own sutures. The ones that removed the sutures did so without difficulty or complications.

TISSUE ADHESIVE CLOSURE (CYANOACRYLATES)

Tissue adhesives (skin glues) are best used to close low-tension, small, straight-edged, and superficial wounds (**Figure 116-22**). They should not be used for lacerations that are bleeding, lacerations over joints, or lacerations under tension. There must be adequate hemostasis and the tissue must be as dry as possible. The major advantage to the use of tissue adhesives is speed. Wounds can be repaired quickly and without anesthesia. Other contraindications to this type of closure are angled or beveled wounds. Petroleum-based ointments or similar products will dissolve the tissue adhesive and should be avoided on this type of closure. Refer to Chapter 117 for a more complete discussion of tissue adhesives.

Tissue adhesives come in a variety of forms and applicator tips (**Figures 116-22A and 116-22B**). Approximate the wound edges

FIGURE 116-20. Reinforcing sutures for wounds under tension. **A.** The front and back sides of the Perchick button. Sterile buttons (**B**) or pieces of sterile rubber tubing (**C**) can be used to secure the suture and prevent injury to the soft tissues.

with forceps. Commercially available, disposable, single-patient-use tissue forceps can be used (Bionix Development Corp., Toledo, OH). These are specifically designed to approximate the wound edges prior to using cyanoacrylates (**Figure 116-22C**). Apply the adhesive in two or three layers along the wound edge (**Figure 116-22D**). The adhesive may also be applied in spots over the laceration (**Figure 116-22E**) or across the laceration, like wound tape (**Figure 116-22F**). Droplets or lines should be placed 0.5 cm from each other. Support the wound for 30 to 60 seconds while the adhesive dries.

The Ethicon Dermabond Prineo (**Figure 116-22B**) is a modification to the use of tissue adhesives. It is a skin closure system that

consists of a flexible, polyester, self-adhering mesh and tissue adhesive pen. This system is supposed to provide a strength greater than suture and staples.

SKIN CLOSURE TAPES

Skin closure tapes (e.g., Steri-Strips) are used to close very-low-tension wounds that are tidy and small.¹⁵ They can be used as the primary closure technique for superficial wounds (**Figure 116-23**) or they can provide reinforcement after sutures have been placed (**Figure 116-24**).¹⁶ Skin tapes are easy to use and can be placed relatively quickly. They do not leave suture marks and have no

FIGURE 116-23. Skin closure tapes to primarily close a laceration.

skin reactivity. They do not improve cosmesis or decrease scar width.¹⁷

Skin closure tapes should not be used in wounds where the edges are widely separated or on parts of the body where there is movement or moisture. This technique does not work well on irregularly shaped wounds or wounds where there will be a propensity for swelling of the wound edges. Care should be taken in using these tapes in a child. If they are not secured properly, the child may remove them prematurely.

After the initial cleansing of the skin, clean the skin surface with acetone or alcohol to remove any surface oils. Allow the skin to dry. Apply benzoin solution or gum mastic (e.g., Mastisol) to the skin on

both sides of the wound (**Figure 116-23A**). Allow 60 to 90 seconds for the liquid benzoin to dry and become tacky. Cut the skin closure tapes to the proper length (**Figure 116-23B**). Gently tear the end-tab off the back of the card to prevent the strips from deforming (**Figure 116-23C**). Remove a strip from the card (**Figure 116-23D**). Firmly secure the tape to one side of the wound (**Figure 116-23E**). Use the nondominant hand to appose the wound edges as the tape is brought over and secured to the skin on the opposite wound edge (**Figure 116-23F**). Place additional tapes at 2 to 3 mm intervals until the wound edges are apposed (**Figures 116-23G and 116-23H**). Place pieces of tape across the tape edges to prevent premature removal and skin blistering from the tape ends (**Figure 116-23I**).

Skin closure tapes may be placed over a sutured laceration (**Figure 116-24**). The tapes will provide additional support to the wound edge and help to prevent dehiscence. This technique is especially useful in areas of cosmetic concern, such as the face.

The skin closure tapes should remain in place for at least as long as the sutures. They must be kept dry to prevent them from coming off prematurely and the wound from dehiscing. The wound should be observed daily for signs of infection.

Skin closure tapes may be placed across a wound when sutures or staples are removed. The tapes will maintain the apposition of the epidermis as the wound matures. Apply benzoin solution to the skin before removing the sutures or staples. Remove several sutures or staples and apply the skin closure tapes. Continue this process until all the sutures or staples have been removed and the wound is covered with skin closure tapes. Alternatively, remove all of the sutures or staples and then apply the skin closure tapes.

FIGURE 116-24. Skin closure tapes can provide reinforcement for sutures.

Suturing lacerations in a thin-skinned individual is often difficult. The skin frequently tears as the wound is approximated and the suture is tied. The use of skin closure tapes can facilitate wound closure by strengthening the skin edges, and allow for a more secure wound closure.¹⁸⁻²⁰ Clean, prep, and anesthetize the skin. Apply benzoin solution to the skin adjacent to and on both sides of the laceration. Allow the benzoin to sit and become tacky. Apply skin closure tapes over the benzoin on both sides of the laceration. Suture the laceration, ensuring that the needle enters the skin on one side of the laceration and exits the skin on the other side of the laceration, through the skin closure tapes on each side. Remove the skin closure tapes at the time of suture removal.

Two advanced skin closure tape-based systems are the ClozeX (Clozex Medical LLC, Wellesly, MA) and the 3M Steri-Strip S Surgical Skin Closure (3M Healthcare, St. Paul, MN). These are nonlatex, disposable, single-patient-use, transparent, adhesive-based wound closure devices for the primary closure of lacerations and wounds not under tension. They align the wound edges and provide good cosmetic results. They come in a variety of sizes, ranging from 10 to 100 mm.

STAPLE CLOSURE

Stapling is a rapid closure technique that is useful for superficial scalp lacerations and linear lacerations of the trunk and extremities.²¹ Staple closure of wounds is cosmetically equal to sutures.²¹ Staples should not be used on the face, neck, hands, or feet. These areas have little subcutaneous tissue and the staples can damage underlying structures. Staples should also be avoided, if possible, in any area of the body that will be exposed to computed tomography (CT) or magnetic resonance imaging (MRI) as they will cause artifact interference on the scan. The staples are made of an inert material, which helps to decrease tissue reactivity. Staples should not be used for wounds that are crush wounds, infected, irregular, macerated, over bony prominences, or under tension.

The skin stapler is a simple device (Figure 116-25). It is a single-patient-use, sterile, disposable unit that is preloaded with staples. It is grasped and held with one hand. When the handle is squeezed, a staple is inserted into the tissue. The stapler automatically loads the next staple after one staple is discharged. Skin staplers typically have 10 or 35 preloaded staples.

Prepare the wound for stapling. Place deep sutures to close the subcutaneous tissue and, if the wound is gaping, bring the wound edges into apposition. Approximate the skin edges with

the dominant hand (Figure 116-26A). Evert the wound edges with a forceps held in the nondominant hand (Figure 116-26A). Grasp the stapler with the dominant hand. Gently place the skin stapler over the laceration (Figure 116-26B). Start at one end of the laceration and work toward the opposite end. **Do not indent the skin with the stapler, as this will cause the staples to be placed too deep.** Align the arrow on the front of the stapler over the laceration (Figure 95-26C). Squeeze the handle of the stapler. A plunger will advance a staple into the wound margins (Figure 95-26D). An anvil will bend the staple into a square or rectangular shape to secure the staple (Figure 95-26E). Continue to evert the wound edges and apply staples every 3 to 5 mm until the wound is approximated and without any gaps (Figure 95-26F). A small space will be visible between the skin surface and the staple if it is properly positioned. If the staple is against the skin, it has been placed too deep. Remove the staple and replace it.

There are a few complications associated with staple use. Their removal can be uncomfortable or difficult. Minor bleeding can occur from the holes after the staples are removed. Staples placed on the face, feet, hands, and neck can damage superficial subcutaneous structures (e.g., blood vessels, muscles, nerves, and tendons). Improper wound eversion can result in wound dehiscence upon staple removal, larger scars, and poor wound healing. Staples can cause larger and more prominent skin marks and subsequent scarring when compared to sutures.

STAPLE REMOVAL

Staples should remain in place for approximately 5 to 10 days, the same amount of time as sutures. They can remain longer if placed over a joint or in cases of slow wound healing. The staple remover is a disposable, sterile, single-patient-use device (Figure 116-27A). It is made of metal or plastic with metal tips. The lower jaw of the stapler has two upwardly angled metal prongs (Figures 116-27B and 116-28). The upper jaw of the stapler is a flat piece of metal. Insert the prongs of the lower jaw of the staple remover between the staple and the skin (Figure 116-28A). Close the handles of the staple remover. This will cause the upper jaw to compress the center of the staple and the arms of the staple to withdraw from the skin (Figure 116-28B). Lift the staple remover and staple off of the skin. Discard the staple and continue the process until all the staples have been removed. **A patient who plans to follow-up in a clinic or office should be given a staple remover to take with them, as many clinics and offices do not routinely stock these devices.**

HAIR APPPOSITION

A

B

FIGURE 116-27. The staple remover. **A.** Overview. **B.** The tip with the jaws open.

Scalp wounds can be closed using hair-tying, also known as the hair apposition technique (HAT).²²⁻²⁷ This technique is relatively painless, does not usually require anesthesia, results in a shorter procedure time, eliminates the need for staple or suture removal, is cost-effective, and the wound outcome is similar or superior to sutures.^{22,23,26} This technique should not be used on wounds under tension, wounds with ongoing hemorrhage, wounds that are grossly contaminated, or if the hair is less than 3 cm in length.

Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp three to four hairs on each side of the laceration (**Figure 116-29A**). Twist the

Twist the hair strands on each side of the laceration to form a single “rope.” **B.** Cross the hair ropes to opposite sides of the laceration. **C.** Twist the two “ropes” of hair together to close the wound and appose the wound edges. **D.** Apply tissue adhesive to the twisted hair and apposed skin segment of the laceration.

hair strands on each side of the laceration to form a single “rope.” Tie the two “ropes” of hair together to close the wound and appose the edges (**Figure 116-29B and 116-29C**). Use a hemostat and an instrument tie to make the process simpler and easier. Continue this process until the entire laceration is closed with hair ties. As the laceration heals, the hair knot will grow away from the wound edges. The hair knot can be cut off by a family member, friend, or primary care provider in 2 to 4 weeks.

An alternative HAT uses tissue adhesive instead of making a hair knot (**Figure 116-29**).²⁶ Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp three to four hairs on each side of the laceration. Twist the hair strands on each side of the laceration to form a single “rope.” Twist the two “ropes” of hair together to close the wound and appose the edges. Apply tissue adhesive to the twisted hair and apposed skin segment of the laceration (**Figure 116-29D**). Allow 30 seconds for the tissue adhesive to dry. Apply a second layer of tissue adhesive and allow it to dry. Continue this process until the entire laceration is closed. This method does not require the later cutting away of the hair knot due to the tissue adhesive breaking down in 7 to 10 days.^{26,28} Unfortunately, this technique may not produce as much hemostasis or wound eversion as tying a hair knot.²⁶ Refer to Chapter 117 for more details regarding tissue adhesives.

MISCELLANEOUS WOUND CLOSURE DEVICES

ABSORBABLE WOUND CLOSURE DEVICES

The V-Loc (Covidien, Norwalk, CT) is a disposable, single-use, unidirectional barbed wound closure device (**Figure 116-30**).

FIGURE 116-30. The V-Loc Wound Closure Device. (Photo courtesy of Covidien Inc.)

It comes in three forms; two are absorbable (**Table 116-1**) and one is nonabsorbable (**Table 116-2**). The proximal end is the suture needle attached to an absorbable barbed suture. The distal end is a fixed loop of the suture material. This self-anchoring loop and barb combination eliminates knot tying when closing wounds. It is placed similar to a running subcuticular stitch. The barbs are circumferentially distributed on the suture strand and spread tension evenly across the wound. This device is mostly used for postoperative skin wounds but may become more popular in the Emergency Department. A similar device is the Stratafix (**Figure 116-31**) (Ethicon, Neenah, WI). Both are modifications of suture.

INSORB SUBCUTICULAR SKIN STAPLER

The InsoRB subcuticular skin stapler (Incisive Surgical, Plymouth, MN) combines absorbable sutures and a device similar to a skin

FIGURE 116-31. The Stratafix Wound Closure Device. **A.** Overview. **B.** Close up of the barbs. (© 2016 Ethicon, Inc. Reproduced by permission.)

(Photos courtesy of Incisive Surgical Inc.)

stapler (**Figure 116-32**).^{29,30} It has the advantages of a subcutaneous closure with the speed of a stapler. This is a sterile, single-patient-use device that deploys up to 20 absorbable subcutaneous staples (**Figure 116-32A**). The subcutaneous staples are horseshoe shaped (**Figure 116-32B**). The device allows wound eversion with no external sutures or metal staples that require later removal (**Figures 116-32C and 116-32D**). It also comes in a Shorty version that is smaller and easier to hold (**Figure 116-32E**). The final cosmetic results are similar to sutures or skin staples.³¹ The company also sells a reusable three-arm proprietary forceps to make wound approximation easier for one person.

DYNACLOSE DYNAMIC TISSUE SYSTEM

Dynaclose Dynamic Tissue System (Southmed, Ontario, Canada) was developed for use by Surgeons in the Operating Room (**Figure 116-33**). Dynaclose provides an easy, painless, and noninvasive method to close retracted or dehiscent wounds up to 5 cm in width. It acts dynamically, moving with skin as it is stretched, while always providing a consistent appositional force. The clear elastomeric strip is anchored by an adhesive fabric tape on either side (**Figure 116-33**). The Dynaclose looks similar to larger Steri-Strips. It can be used in the Emergency Department for wounds

FIGURE 116-33. The Dynaclose Dynamic Tissue System. (Photo courtesy of Southmedic.)

under tension. Apply the Dynaclose strips to approximate the wound edges before suturing. It can also be applied after suturing to reinforce the repair.

ZIPLINE SKIN CLOSURE DEVICE

The Zip Surgical Skin Closure Device (Zipline Medical, Campbell, CA) is a noninvasive alternative to staples, sutures, and glue for the skin (**Figure 116-34A**). A strong yet gentle hydrocolloid skin adhesive attaches the device on either side of the wound (**Figure 116-34B**). Integrated adjustable straps are tightened to close the wound. The straps are also reversible if the wound is over-tightened during closure. The excess straps are cut with scissors (**Figure 116-34C**). This prevents patient tampering and disengagement. The device is flexible to move with body movement. It is typically kept on the wound for 7 to 14 days and can be removed at home by the patient. There are several benefits to this device. They include a shortening of the procedure time, a simple application process, no need for injected anesthesia, minimization of needle anxiety, a large force distribution area on the skin, and no need for follow-up visits for suture removal. It is useful for elderly or thin skin that may be challenging to suture. The device can be applied to a curved incision and several devices may be applied to very long incisions. The device may also be cut with scissors for shorter incisions. It is available in four lengths, suitable for closure of incisions up to 4, 8, 16, and 24 cm in length.

FUTURE INNOVATIONS

In the near future, there may be innovations available to the Emergency Physician.^{32,33} An automated suturing device being developed by Suttrue streamlines the suturing process. It is available in multiple needle sizes. This device has the advantages of preventing needle-stick injuries, speed of suture placement, and no variation in placement, and has a backward option. Another device heat seals straight wounds very quickly.

SUMMARY

There are multiple techniques available for closing wounds. The principles and techniques discussed will help to provide the most appropriate closure for the various types of wounds that are seen in the Emergency Department. Care should be taken to provide the best closure possible to provide good cosmesis and avoid complications.

Tissue Adhesives for Wound Repair

Hagop M. Afarian

INTRODUCTION

The year 1942 marked the discovery of cyanoacrylate, the chemical found in adhesives such as Superglue.¹ The use of cyanoacrylates for wound closure has been described since the 1960s when it was first assessed for military use. It was not until 1998 that N-2-octylcyanoacrylate (i.e., Dermabond) was approved by the Food and Drug Administration (FDA) for use in the United States. Tissue adhesives have since redefined the overall approach to laceration repair, especially in the Emergency Department. Their ease of use, relative painlessness, and simplicity of after-care make it an ideal tool for small straight wounds and use in children.^{2,3} There has been an increase in companies producing topical tissue adhesives for wound closure (Table 117-1).

ANATOMY AND PATHOPHYSIOLOGY

Cyanoacrylates are a monomer liquid. They polymerize when activated by water via an exothermic reaction to form a strong bond. Heat is released by this polymerization reaction and may cause some discomfort. Cyanoacrylates are classified as either butyl or octyl based on the side chain (Table 117-2).^{4,5} Butyl cyanoacrylates have short and straight side chains. This allows them to form bonds that are poorly flexible, strong, and tight. Unfortunately, these bonds can become brittle and fracture. Butyl cyanoacrylates are best suited for short lacerations under no tension. Examples of butyl cyanoacrylates include Histoacryl (B. Braun, Bethlehem, PA) (Figure 117-1) and Indermil (Syneture, Norwalk, CT) (Figure 117-2). Octyl cyanoacrylates have longer side chains. This allows them to form bonds that are flexible, less likely to fracture, and strong. Octyl cyanoacrylates can be used on lacerations of any length. Examples of octyl cyanoacrylates include Dermabond (Ethicon Corp., Norwood, MA) (Figure 117-3), Exofin (Chemence Medical Inc., Alpharetta, GA) (Figure 117-4), and SurgiSeal (Pfizer Inc., New York, NY) (Figure 117-5). Newer agents are a combination of the strong and fast-setting butyl cyanoacrylates with the flexibility of the octyl cyanoacrylates. An example is LiquiBand (Advanced Medical Solutions Inc., Plymouth, United Kingdom) (Figure 117-6).

The nonmedical and medical adhesives contain similar ingredients. The differences between these two types are sterile production, sterile packaging, and the attached alcohol chain in medical grade tissue adhesives. Converting a methyl to an octyl group reduces the heat produced by polymerization and decreases the amount of direct tissue inflammation caused by the breakdown products of the adhesive.^{1,6,7}

TABLE 117-1 Some Commercial Tissue Adhesives

Tissue glue	Name	Manufacturer
Butyl cyanoacrylate	Glubran 2	GEM SRL
	Histoacryl	B. Braun
	Indermil	Syneture
	LiquiBand	Advanced Medical Solutions
	SkinLink	Advanced Medical Solutions
Ethyl cyanoacrylate	EpiGlu	Meyer-Haake
Octyl cyanoacrylate	Dermabond	Ethicon
	Exofin	Clemence Medical
	SurgiSeal	Pfizer

TABLE 117-2 Comparison of Butyl Cyanoacrylate and Octyl Cyanoacrylate		
Characteristic	Butyl cyanoacrylate	Octyl cyanoacrylate
Degradation	Slow	Slower
Exothermia	Most	Less
Flexibility	High	Higher
Setting	60–90 seconds	Quicker
Strength	Strong	Strongest

There are many advantages to tissue adhesives.^{8–10} The major advantage to the use of tissue adhesives is speed. Wounds can be repaired quickly and without anesthesia. Tissue adhesives have been shown to offer similar wound closure and cosmetic results as adhesive strips (e.g., Steri-Strips) and sutures.^{11–14} The initial tensile strength of wounds repaired with tissue adhesives are not equivalent to wounds closed with sutures.^{15,16} Within 7 days any differences in tensile strength are no longer present.^{15,16} The cost to the patient is less for lacerations repaired with tissue adhesives compared to suturing.^{12,17} This accounts for materials, physician time, procedure time, and repeat visits for suture removal.^{14,17} There is less need for the painful injection of local anesthetic solution. The risk of a needle-stick injury to the Emergency Physician is decreased when not suturing. An additional benefit of tissue adhesives is that they provide an occlusive covering for wounds, keep wounds moist, keep wounds water tight, and provide protection from invading microbials.¹⁸ Wounds closed with tissue adhesive do not require routine follow-up like those sutured closed for suture removal.

There are also disadvantages to using tissue adhesive.^{3,10} There is a variability among Emergency Physicians using the adhesive. Their skill varies as well as their experience. It may be difficult to appose skin edges and evert wound edges. Wounds may dehiscence over time because the effectiveness of tissue adhesives over time is lost. There is poor reliability among tissue adhesive when compared to sutures. Placement of and removing topical adhesives can damage the epidermis.

INDICATIONS

Tissue adhesives are best used to close low-tension, small, straight-edged, and superficial wounds. Use precautions when using tissue adhesives near the eye. The liquid adhesive can run into the eye. The tissue adhesive can cause iatrogenic sealing of the eyelids if the eyelid margins are not protected.¹⁹ Tissue adhesive may be used for wounds that are deep or under tension as a superficial closure layer only after the subcutaneous layer has been repaired to bring the wound edges together and relieve tension.

FIGURE 117-1. Histoacryl (B. Braun, Bethlehem, PA).

FIGURE 117-3. Dermabond Advanced (Ethicon Corp., Norwood, MA).

FIGURE 117-4. Exofin (Clemence Medical Inc., Alpharetta, GA).

FIGURE 117-5. SurgiSeal (Pfizer Inc., New York, NY). The stylus pen (left), teardrop applicator (right), and twist top (bottom).

Most wounds on the head, neck, proximal extremity, and torso can be closed with tissue adhesive. Flap-type lacerations and lacerations of thin skin can be closed where the use of sutures can compromise the skin. Long lacerations can be divided into segments and each segment closed as if it were a small laceration.¹³ Consider using tissue adhesives on abrasions that keep oozing.²⁰

CONTRAINDICATIONS

Tissue adhesives should not be used on wounds that are actively infected, heavily contaminated, greater than 6 to 12 hours old, from a crush injury, punctures, on the eyelids or surrounding skin, or from bites. **Tissue adhesives can only be used on the skin surface and not within wounds, on mucous membranes, or on mucocutaneous junctions (e.g., the mouth and lips).** Do not use tissue adhesives on patients with a known hypersensitivity to cyanoacetate and formaldehyde, as cyanoacrylates degrade into these byproducts. It is recommended that tissue adhesives not be used in areas of the body that are exposed to heavy moisture (e.g., the perineum and axilla) and parts of the body prone to frequent movement (e.g., hands, feet, and over joints).²¹ **Wounds must be dry.** Do not use tissue adhesives on wounds that are actively bleeding or oozing. Tissue adhesive use in these areas may lead to wound dehiscence as the adhesive cracks and/or peels.²¹ Stop the bleeding with direct pressure or the injection of local anesthetic solution with epinephrine prior to the application of tissue adhesive. Tissue adhesive may be difficult to use in areas covered densely with hair (i.e., the scalp and axilla) since the tissue adhesive will not bond adequately to the skin. Tissue adhesives are not recommended for stellate wounds because of the difficulty of adequately approximating the many wound edges. Other contraindications to this type of closure are angled or beveled wounds, unless deep sutures are first placed to approximate the wound edges and relieve any tension.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Gloves
- Tissue adhesive
- Wound cleaning and irrigation supplies (Chapter 114)
- Forceps
- Petroleum jelly
- Acetone or nail polish removal pads
- Gauze squares
- Occlusive dressing (e.g., Tegaderm)

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed consent for the procedure. Anesthetize the wound. Cleanse the wound and surrounding skin of any blood, dirt, and debris. Irrigate the wound with normal saline or tap water. Consider using a wound irrigation device as described in Chapter 114 if the wound is dirty. Injuries that require substantial cleaning may not be good candidates for tissue adhesive closure. Inspect the wound for any retained foreign bodies or injuries to deep structures. **All bleeding must be controlled prior to the application of the wound adhesive.** Repair lacerations with continued or heavy bleeding with sutures to achieve adequate hemostasis. Dry the skin surrounding the laceration with gauze squares.

FIGURE 117-6. LiquiBand (Advanced Medical Solutions Inc., Plymouth, UK).

TECHNIQUES

GENERAL TISSUE ADHESIVE TECHNIQUE

The general technique will be described. There are some differences in the type of applicator. Prepare the tissue adhesive. Some only require the removal of a twist-off plastic cap. Others are supplied in ampules that must be crushed and allowed to soak the foam tip of the applicator. Use the tissue adhesive immediately after opening the container as it dries within minutes and may not continue to flow freely for long. Tissue adhesives dispensers are available with a variety of applicator tips (Figures 117-1 through 117-6).

Approximate the wound edges with forceps. Commercially available, disposable, single-patient-use tissue forceps can be used (Bionix Development Corp., Toledo, OH). These are specifically designed to approximate the wound edges prior to using tissue adhesives (Figure 117-7). Alternatives to these devices are Adson forceps or using gloved fingers. Place a thin layer of tissue adhesive over the wound and extending 5 to 10 mm beyond the wound margins (Figure 117-8A). The tissue adhesive may also be applied in spots over the laceration (Figure 117-8B) or across the laceration like wound tape (Figure 117-8C). Apply the droplets or lines of tissue adhesive approximately 0.5 cm from each other. **Hold the wound edges together for 30 to 60 seconds following the application of the first layer of tissue adhesive to allow for optimum polymerization.**

FIGURE 117-7. Commercially available wound forceps (Bionix Development Corp., Toledo, OH).

FIGURE 117-8. Laceration repair with tissue adhesive. **A.** Tissue adhesive applied continuously over the laceration. **B.** Tissue adhesive applied in spots over the laceration. **C.** Tissue adhesive applied across the laceration.

Apply a total of three to four thin layers of tissue adhesive. Allow each layer to dry for approximately 30 to 60 seconds before applying the next layer. Each successive layer will take longer to dry as the water available for the polymerization reaction has been covered by the previous layer. **Be careful to use only thin layers and not large drops of adhesive to assist drying time and prevent discomfort from any heat released by the exothermic polymerization reaction. Do not allow the tissue adhesive to flow into the wound.** It can remain in the wound long after the skin has healed leading to delayed healing, prolonged inflammation, and tattooing.⁴

Do not touch the layers of wound glue as they are drying to prevent cracking and inadvertent adhesion of gloves or foreign bodies to the wound. Gently peel gloved fingers away from the most recent layer before it dries if they or other foreign bodies have become

attached to the wound. Use poly gloves if available. These are used by food service workers and tissue adhesive does not stick. Wipe away tissue adhesive applied to an area where it does not belong within 10 seconds.

PREVENTING THE TISSUE ADHESIVE FROM RUNNING

Techniques have been described for use when working around areas that must not contact the tissue adhesive (e.g., the eye). The first and easiest precautionary technique is patient positioning. Position the patient so that the tissue adhesive will not run away from the wound. Ideally, the wound surface should be parallel to the floor. Unfortunately, this is not always possible to accomplish. Alternatively, position the patient in a manner such that the wound rests below the sensitive area. Gravity allows any of the liquid tissue adhesive to run away from the area of concern. Avoid squeezing the tissue adhesive container too much to control the amount expressed. This can help to minimize any runoff. Consider placing a piece of gauze or a clear occlusive dressing (i.e., Tegaderm) over the area of concern to protect it from any runoff.

A barrier can be created between the wound and the sensitive area. Place a thin film of petroleum jelly between the wound and the sensitive area. This will ensure that if the tissue adhesive were to run, it will not spread beyond the barrier. Alternatively, apply the petroleum jelly in a wide circle surrounding the wound and create a valley for the tissue adhesive to fill if it runs. It may become difficult to hold the wound edges together in a small space covered with petroleum jelly. The oil-based petroleum jelly may prevent adequate binding of the tissue adhesive if the jelly gets on the skin immediately adjacent to the wound.

A final technique to keep the wound adhesive from running is the use of an occlusive dressing (e.g., a Tegaderm) (**Figure 117-9**).²² Obtain an occlusive dressing large enough to cover the area in question (**Figure 117-9A**). Fold the dressing in half (**Figure 117-9B**). Cut a hemi-ellipse out of the dressing (**Figure 117-9C**). Unfold the dressing and center the cut-out ellipse over the wound (**Figure 117-9D**). Make sure that the newly created hole in the center is large enough to include the entire laceration and some surrounding skin. Cut additional material from the dressing if needed. Remove the protective tape from the back of the dressing and apply it to the skin. Approximate the wound edges and apply tissue adhesive (**Figure 117-9E**). Cover the entire precut hole and some of the surrounding dressing with the tissue adhesive. Allow the layers of tissue adhesive to completely dry. When removing the dressing be careful not to disturb the freshly adhered tissue adhesive. A useful technique is to pull apart the dressing from the center outward, stretching it away from the edge of the adhesive. This allows it to release from the tissue adhesive without causing the adhesive to peel. The result is a well-demarcated, circular film of tissue adhesive overlying the closed laceration (**Figure 117-9F**).

FIGURE 117-9. The use of an occlusive dressing for protection of nearby sensitive structures when using tissue adhesives. **A.** The occlusive dressing. **B.** The dressing is folded in half. **C.** A hemi-ellipse is cut out of the dressing. **D.** The dressing is opened with the cut-out ellipse centered over the wound. The protective tape is removed and the dressing adhered to the skin. **E.** The wound is approximated and tissue adhesive is applied. **F.** The result after the dressing has been removed reveals a well-circumscribed area of tissue adhesive.

FIGURE 117-10. The hair apposition technique (HAT) to close a scalp laceration. **A.** Grasp 5 to 15 hairs on each side of the laceration. Twist the hair strands on each side of the laceration to form a single “rope.” **B.** Cross the hair ropes to opposite sides of the laceration. **C.** Twist the two “ropes” of hair together to close the wound and appose the wound edges. **D.** Tissue adhesive is applied to the twisted hair and apposed skin segment of the laceration.

HAIR APPPOSITION TECHNIQUE

Scalp wounds can be closed using hair-tying, also known as the hair apposition technique (HAT).²²⁻²⁷ This technique is relatively painless, does not usually require anesthesia, results in a shorter procedure time, eliminates the need for staple or suture removal, is cost-effective, and the wound outcome is similar or superior to sutures.^{23,24,27} Do not use this technique with wounds under tension, wounds with ongoing hemorrhage, wounds that are grossly contaminated, or if the hair is < 3 cm in length.

Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp 5 to 15 hairs on each side of the laceration (**Figure 117-10A**). Twist the hair strands on each side of the laceration to form a single “rope.” Tie the two “ropes” of hair together to close the wound and appose the edges. Use a hemostat and an instrument tie to make the process simpler and easier. Apply tissue adhesive to the hair knot for added security. Continue this process until the entire laceration is closed with hair ties. The hair knot will grow away from the wound edges as the laceration heals. The hair knot can be cut off by a family member, friend, or primary care provider in 2 to 4 weeks.

An alternative HAT uses tissue adhesive instead of making a hair knot.^{27,28} Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp 5 to 15 hairs on each side of the laceration with gloved fingers or a hemostat (**Figure 117-10A**). Twist the hair strands on each side of the laceration to form a single “rope.” Twist the two “ropes” of hair together to close the wound and appose the edges (**Figures 117-10B and 117-10C**). **Do not wind the strands more than one turn to prevent increased tension and tissue necrosis.** Apply tissue adhesive to the twisted hair and apposed skin segment of the laceration (**Figure 117-10D**). **Do not allow the tissue adhesive to run into the wound.** Allow 60 to 90 seconds for the tissue adhesive to dry. Apply a second layer of tissue adhesive and allow it to dry. Continue this process until the entire laceration is closed. This method does not require the later cutting away of the hair knot. This technique may not produce as much hemostasis or wound eversion as tying a hair knot.²⁷

PRINEO SKIN CLOSURE SYSTEM

The Prineo Skin Closure System (Ethicon Corp., Norwood, MA) is a octyl-2-cyanoacrylate used with a self-adherent mesh (**Figure 117-11**).^{8,29} The mesh is applied after the wound margins

are apposed. The self-adherent mesh will hold the wound edges together and eliminates the need for manual apposition using fingers. This simplifies wound closure and gets the fingers out of the location of the wound. A single layer of tissue adhesive is needed due the mesh. Use of the Prineo Skin Closure System was faster and equivalent to using suture.^{8,29} Patients can have allergic local reactions to the adhesive or the mesh.³⁰⁻³²

PEDIATRIC CONSIDERATIONS

Pediatric patient movement is the factor that causes the greatest difficulties when working with wound adhesives. Tissue adhesives are most useful in the pediatric population, but this population has the greatest risk of movement. Movement will permit running of the adhesive and leakage onto uninvolved areas. Use extra caution when working around sensitive areas. Use a high-viscosity tissue adhesive to limit leakage when working around sensitive areas or on children who have trouble remaining still (**Figure 117-12**). Children may pick at the edges of the newly formed adhesive covering and cause it to become dislodged prematurely. Applying a dressing will help alleviate this risk. Consider using LET (lidocaine, epinephrine, and tetracaine) (Chapter 154) if anesthesia is required.³³

ASSESSMENT

Assess the closed wound to ensure that the edges are approximated. Tissue adhesive that has adhered and dried on uninvolved areas may be removed using petroleum jelly or topical petroleum-based antibiotic ointment. Apply the oil-based jelly or ointment to the dried tissue adhesive and let it stand for 30 minutes. Gently peel away the tissue adhesive. Use acetone or nail polish remover pads to remove the tissue adhesive more quickly instead of waiting the time for the oil-based products to work.³⁴ **Be careful to not let acetone drip into the eye or on mucous membranes.**

Tissue adhesive occasionally does enter the eye or the eyelids become glued shut (**Figure 117-13**).^{35,36} Tissue adhesives are not toxic to the globe and will not cause damage to the conjunctiva or cornea. **Do not attempt to pry open the eyelids or cut between the eyelid margins to separate the eyelids.** Apply an ophthalmic antibiotic ointment to the eyelids if they are sealed shut. Allow the ointment to sit for 30 minutes. Instruct the patient to open their eyelids. Gently wipe the ointment and adhesive from the eyelids if the patient can open their eyelids. Instruct the patient to apply the ophthalmic ointment 5 to 6 times a day at home and gently attempt

FIGURE 117-11. The Prineo Skin Closure System (Ethicon Corp., Norwood, MA). **A.** The parts of the system. **B.** Wound approximation and placement of the mesh. **C.** Application of the tissue adhesive. (Used with permission from reference 8.)

to open their eyelids if they cannot open their eyelids in the Emergency Department. Their eyelids will separate within 2 to 3 days.

AFTERCARE

Instruct the patient not to use oil-based substances on any wound repaired with tissue adhesives.¹ Tissue adhesive does not need to be removed. It will peel away within 5 to 10 days as new epithelial layers are formed below it. Wounds repaired with tissue adhesive may briefly contact water (e.g., showering) but should not be scrubbed clean. Do not soak the wound (e.g., a bath tub, pool, or spa). Instruct the patient to return immediately to the Emergency Department or to their primary care provider for any signs of a wound infection.

COMPLICATIONS

Many of the complications associated with the use of tissue adhesives are preventable. The Emergency Physician must choose the proper patient, the proper wound, and the appropriate wound location. These few things in association with the appropriate tissue adhesive application technique will avoid most complications. Tattooing of the scar can occur from the adhesive, a foreign body in the wound, or not cleansing the wound thoroughly.³⁷ The details of these have been described previously in the indications, contraindications, and techniques sections.

A certain percentage of repaired wounds will become infected. Minimize any infections by properly preparing the wound

FIGURE 117-12. High-viscosity tissue adhesive can be used routinely to prevent the adhesive from running and in children.

(Chapter 114). This includes the use of anesthesia if appropriate, wound irrigation, wound debriding, wound undermining, wound exploration for foreign bodies, and the use of deep sutures to release tension.

SUMMARY

Tissue adhesives have changed the face of laceration repair. Wounds are repaired more quickly with tissue adhesives and often at a lower cost compared to suturing. Patient satisfaction is increased. There are very few limitations to the use of tissue adhesives. Proper patient selection, proper wound selection, and proper wound preparation will minimize any complications.

Advanced Wound Closure Techniques

Eric F. Reichman

INTRODUCTION

Traumatic wounds or skin lacerations are among the most common injuries, occurring in people of all ages, that require evaluation and treatment in the Emergency Department. The result of many, if not all, wound closures is scar formation. Most wounds heal with a surprisingly pleasing cosmetic transformation from their initial presentations. It is not uncommon for some wounds to present complications during the healing period as well as to produce an undesirable scar. A systematic approach to wound management serves to help in deciding how to close complicated wounds, reduce the risk for infection, and minimize less favorable outcomes.

Wound management in the Emergency Department includes an assessment of the mechanism and conditions that were present at the time of injury. Initially, one must address the concerns of the patient, family members, or friends with a concise explanation of how the wound will be treated and what can be anticipated for aftercare. Many lawsuits and concerns of poor care evolve from poor cosmetic outcomes. **It is recommended that verbal wound care instructions be offered once wound closure is completed, in addition to giving the patient written discharge instructions.**¹

Regardless of the severity of the wound or possible inherent complications associated with the injury, many patients are primarily concerned with the potential for scarring or disfigurement. Most patients expect cosmetic and functional perfection as an ultimate result after their wounds are treated and the healing process is completed. These expectations are often not clearly expressed during the evaluation and treatment in the Emergency Department. **The Emergency Physician must openly explain and discuss the fact that virtually no wound heals without a scar following wound closure.**^{1,2} A clear understanding of this is not to be used as an explanation for a poor outcome but to counter any misconception that a wound will heal to look exactly like the previously intact skin. **Treatment is rendered to offer the best possible functional and esthetic outcome while reducing the risk of potential soft tissue infection.**

An overall plan of wound site preparation and closure will be needed to provide the greatest likelihood of a pleasing cosmetic

result.¹ The mechanism of injury, severity of the wound, location of the wound, and presence or risk of necrotic tissue can all influence the risk of infection. Additionally, the decision of how to approach wound closure will be affected by the patient's skin type, age, gender, occupation, and hobbies.

Wound healing ultimately takes place over at least 6 to 9 months. Any wound presenting with concerns for a poor outcome or an obvious likelihood of wound revision in the future should be evaluated and treated by a Plastic Surgeon when possible.^{1,2} All other wounds requiring complex closures should be properly assessed and treated by the Emergency Physician.

ANATOMY AND PATHOPHYSIOLOGY

To have a better understanding of scar tissue formation and the antecedent techniques of wound closure, the Emergency Physician should have knowledge of specific physiologic conditions and anatomic areas that may increase the chances of unfavorable scarring following wound repair.^{2,3} The age of the patient and appearance of the patient's intact skin should be taken into consideration. The younger patient tends to heal more rapidly, while the older patient tends to have a more favorable cosmetic outcome with wound closure. Older patients have less overall elastic and subcutaneous tissue and more wrinkling, thus decreasing the tension on the healing wound and making scarring less noticeable.^{2,3} Wrinkling, or lines of minimal tension, makes wound repair more technically challenging.

Suturing of asymmetrical, deep, or large wounds requires particular attention to the preexisting lines of minimal tension or lines of facial expression. Without properly addressing such preexistent anomalies, the cosmesis of wound repair can be grossly affected.^{2,3} Scars from wounds closed perpendicular to preexisting functionally anatomic lines undergo repetitive physical stress and may result in hypertrophic scar tissue. With markedly less skin elasticity and subcutaneous fat, older patients will often experience more favorable cosmetic results from less complex wound closures. However, younger patients will benefit from more advanced wound closure techniques to properly close large or complicated wounds. Rotational and advancement flaps are frequently performed to make scarring less obvious when suturing across lines of tension.³

The type of skin, regardless of age, will affect scar formation.^{3,4} Oily or hyperpigmented skin more frequently has poor scar tissue formation. This results in scars that are hypertrophic, deep, and asymmetrical. Consideration of wound outcome should be given to areas of the skin that are rich in sebaceous glands or simply hyperpigmented (e.g., from environmental exposure or ethnicity). Patients with underlying connective disease disorders or conditions with a high likelihood of concomitant vitamin deficiencies should also be scrutinized, as wound closure and healing may be compromised in such cases, resulting in highly variable and less predictable outcomes.

The mechanism of injury, including environmental exposure to underlying tissue, should not be overlooked so that adequate debridement and preparation may be done prior to a complex wound closure. This allows the Emergency Physician to better visualize the anatomic layers of the skin. It can be difficult to determine a clear delineation between the anatomic layers of the skin when the wound was a result of a crush injury, shredding mechanism, or any circumstance resulting in uneven or macerated wound edges. Delineate the pigmented epidermis from the thicker underlying dermis, especially when multilayer wound closures are required, as suturing may then become unnecessarily complicated and affect the overall integrity of the wound closure.

It should be noted that the literature supports a significant underutilization of multilayer closures, although these are often necessary. Single-layer closures and excessively large suture materials are the greatest causes of residual scar tissue.¹ It is recommended to prepare the wound edges by creating a bevel or undercutting of the wound margin to allow subtle epidermal eversion, thus augmenting the natural process of scar formation.^{1,2} This allows the natural flattening and depression of the forming scar to occur without excessive depression from the wound margins.² This will also help to reduce the thickness of the scar tissue and decrease the refraction of light from the scar, making it less noticeable.

Depending on the presentation of the tissue defect, more than one wound closure technique may be used to adequately close a wound. Using more than one technique will help remove underlying tension and allow better approximation of the epidermis. With the help of specific camouflage techniques used in closing the epidermis, irregularly shaped wounds can heal with less obtrusive scarring. Familiarity with a few of these techniques and their application will allow the Emergency Physician to comfortably close the more challenging wounds encountered with expectantly more favorable cosmetic prognoses.

INDICATIONS

Advanced wound closure techniques are indicated for closing wounds with irregularly shaped defects or defects too large for primary closure. They can be used to close circular, square, elliptical, or asymmetrical skin defects. Advanced wound closure techniques are beneficial when there is a need to reduce skin tension and contracture, which are likely to result in hypertrophic scar formation.^{3,4} Rotational and advancement flap techniques are useful in areas where tissue loss must be avoided and the undermining of wound edges must be minimized. This is often encountered with facial wounds in proximity to the eyelids, eyebrows, canthi, nasolabial folds, or lip borders. These techniques allow the initial shape of the wound to be altered such that there is reduced tension on the wound edges, which may then be closed simply.

CONTRAINDICATIONS

Specific wound closure techniques should take into account the potential for scar formation to occur in an undesirable location. This can happen when a wound must be elongated to create parallel lines and to decrease the tension on the wound edges. Elongation of a wound may bring it into proximity of other anatomic positions or landmarks, thus further complicating the healing process. If not planned well, excessively large defects may result, making it more likely that the scar will require later revision. More obvious conditions may exist that compromise complex wound closures. Particular attention must be given to crush injuries with devitalized or contaminated tissues. Severely contaminated wounds, including those with prolonged exposure, generally are at greater risk of infection with multilayer closures. Do not perform these techniques if the patient is at risk for poor wound healing (i.e., diabetes, poor vascular supply to the area, or prior radiation therapy to the area), keloid formation, or coagulopathic. Careful wound assessment may result in a decision to use simple approximation of the wound edges with close follow-up for ongoing wound care. Contraindications to complex wound closures will at times be reliant on temporal factors, such as the need to close a wound prior to the patient receiving surgical intervention for more life-threatening injuries. There must be a commonsense approach in deciding how to close more challenging wounds in the Emergency Department.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Needle drivers, 4.5 and 6.0 inch
- Skin hooks
- Scalpel blades (#10, #11, #15)
- Scalpel handles
- Iris scissors, straight 4 inch and curved 4 inch
- Suture scissors, 6 inch
- Forceps, toothed Adson
- Metzenbaum scissors, curved 6 inch
- Hemostats, straight 6 inch and curved mosquitoes
- Suture material, various sizes and shaped needles
- Skin closure tapes
- Benzoin solution, swabs or spray
- Tissue adhesive
- Tissue adhesive forceps
- Gauze 4×4 squares
- Overhead light source or headlight
- Loupes or magnifying glasses (optional)

The above equipment can be purchased in single-use, sterile, and disposable plastic surgery wound kits from several commercial manufacturers. These kits tend to be expensive and occasionally have a limited amount of equipment. Many hospitals package and sterilize their own wound repair kits. This decreases the cost as the equipment can be repeatedly sterilized and reused. It also allows the kits to contain a wide variety of instruments for multiple situations (e.g., minor lacerations, large lacerations, and plastics closures).

Needle drivers come in a variety of sizes. A 4.5 inch needle driver can be used comfortably with most types of needles. A 6 inch needle driver may be required if large needles are used to close a wound. Hold the needle driver with the fingertips to provide greater flexibility. The fingers can also be placed through the finger holes, but this is not as efficient when closing a wound. Grasp the needle one-third of the way from the swag (distal) end with the tip of the needle driver.

The skin must be grasped and manipulated during wound repair to allow for proper suture placement. Forceps are most commonly used to grasp and manipulate the skin. **Smooth (nontoothed) forceps should never be used to grasp skin.** They require the application of a large amount of force to grasp the tissue. This can crush tissue very easily. An Adson forceps is the forceps of choice. It has fine teeth that grasp tissue securely with minimal force.

A skin hook is a sharp, pointed instrument that is inserted into the wound edge and grasps the tissue from the undersurface. It produces a small puncture wound in the subcutaneous tissues and does not penetrate the skin surface. Skin hooks are preferable to forceps as they do not crush tissues. A skin hook is awkward to use at first. The Emergency Physician will most certainly prefer a skin hook to forceps with proper instruction and experience.

Several types of scissors are required for proper wound closure. Iris scissors have sharp, delicate tips for making precise cuts in tissue. They should not be used to cut suture material as this rapidly dulls and nicks the blades. Suture scissors have one blunt tip and one pointed tip. Both blades of the suture scissors are sharp. Suture scissors are used to cut adhesive tape, gauze, rubber drains, and suture material. Metzenbaum scissors should be used to debride heavy tissue, bluntly dissect tissue, and undermine tissue.

Hemostats are used to clamp small vessels that are bleeding, to explore a wound, and to grasp fascia. Hemostats are available in a variety of sizes and styles. A straight 6 inch hemostat is used for most purposes during wound repair. A curved 5 inch mosquito hemostat can be used for small wounds or delicate tissues.

Three different scalpel blades should be available when a wound is being repaired. A #11 blade is used to make stab incisions. It is often used for the incision and drainage of abscesses, cricothyroidotomies, and the removal of small or tight sutures. A #10 blade is used to make straight cuts in the skin and debride wound edges. It is rarely used in laceration repair. A #15 blade is small and curved to allow precise incisions. It is used for excising foreign bodies and wound debridement.

PATIENT PREPARATION

Explain the risks, benefits, and complications of the wound closure to the patient and/or their representative. The risks include poor healing, wound dehiscence, bleeding, pain, a worse scar, infection, loss of the tissue, and the need for further surgery. The benefits include improved cosmesis and wound healing. Alternatives to advanced wound closure include wet-to-dry dressings and allowing the wound to granulate or follow-up with a Plastic Surgeon for closure or a skin graft. Discuss the presence of a visible scar after the repair which may require subsequent revision. Explain the after-care and follow-up. Obtain a signed informed consent for the procedure.

Place the patient in a position of comfort that is equally comfortable for the Emergency Physician. This should allow for appropriate stretcher or seat height, lighting, and maneuverability so that physical obstacles are not a complicating variable during the wound repair. Clean the wound and surrounding skin of any dirt and debris. Flush the wound with normal saline. Apply povidone iodine or chlorhexidine solution to the surrounding skin, not the wound, and allow it to dry. Anesthetize the area using local or regional anesthesia (refer to Chapters 153 through 159).

Examine the wound for obvious foreign bodies or contaminants. Remove these with pressure irrigation using sterile saline. Apply

sterile drapes to demarcate a sterile field. Apply the drapes so that the wound may be approached easily from different angles and without the risk of contaminating the site or any of the materials being used. **There can be a great degree of variability in sterile techniques. Therefore, it is important to note that the best way to avoid wound infections is to employ and maintain consistency with sterile procedures throughout the wound repair.**

TECHNIQUES

Z-PLASTY

It can be challenging to change the axis of orientation of a wound. The reason for changing the orientation of a wound is to create a more functionally and cosmetically pleasing scar. The Z-plasty has been described as a basic technique for scar revision, although its application also proves useful to lengthen and reorient wounds.⁵ Wound lengthening reduces the formation of contractures which often occurs when the wound crosses areas of flexion. The Z-plasty should not be used for wounds from burn injuries where normal skin is not present. It also breaks up a linear scar into an accordion-like scar that has some degree of elasticity.

The Z-plasty is generally described to redirect a wound occurring across a flexion crease, over a joint, or on the face. It requires two incisions that create two triangular flaps with approximately 60° of separation between the flaps, although the angle may vary between 30° and 90° (Figure 118-1).⁵ The greater the angle, the greater is the gain in wound length. Sharper angles increase the risk of necrosis in the tip of the flap. Broader angles result in difficulty in rotating the flaps. Angles of 60° increase the wound length by 75%. Angles of 45° increase the wound length by 50%. Angles of 30° increase the wound length by 25%. **The length of both arms of the incision must be the same length as the wound.** The undermining and separation of the two triangular flaps lengthens the wound and allows it to be reoriented perpendicularly to the original location. Additionally, small Z-plasties may be used in sequence to offset the appearance of straight wounds crossing lines of flexion or where

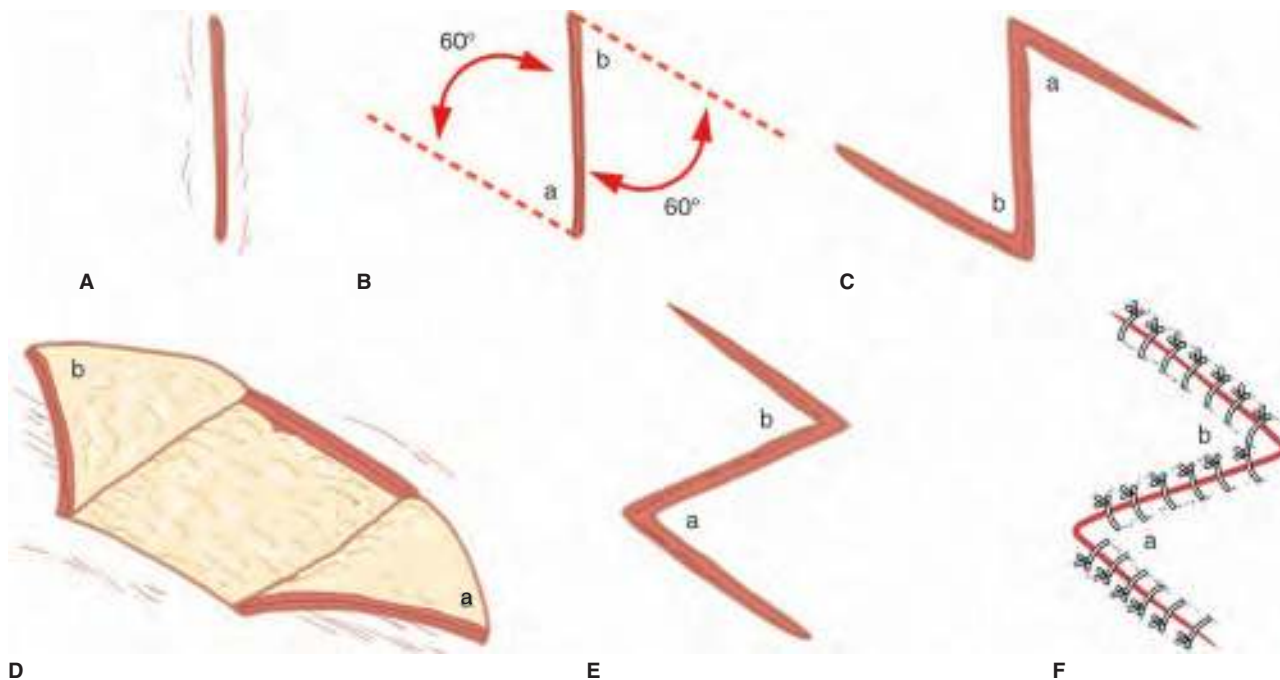

FIGURE 118-1. The Z-plasty. **A.** The original laceration. **B.** Draw the arms of the Z at a 60° degree angle from the ends of the lacerations. The arms must be the same length as the laceration. **C.** The skin has been incised to form the Z. **D.** Undermine and elevate the flaps. **E.** Transpose the flaps to reorient the wound. **F.** Approximate the wound edges with simple interrupted sutures.

FIGURE 118-2. Approximating edges of grossly unequal lengths in repairing a laceration. **A.** The laceration. **B.** Draw an equilateral triangle along the longest side and centered about the widest part of the laceration. The sides of the triangle must be equal to the length of the widest part of the original laceration. **C.** Approximate the wound edges with simple interrupted sutures.

contractures are likely to occur so that the wound site then becomes parallel to the lines of flexion, further reducing occurrence of contracture formation.^{3,4}

Clean, prep, and anesthetize the wound and surrounding skin. If the wound edges are irregular, sharply debride them using a #15 scalpel blade to form straight edges (**Figure 118-1A**). Measure and draw 60° angles from the ends of the laceration (**Figure 118-1B**). Draw the arms of the Z on the patient's skin with a skin-marking pen. **The arms must be the same length as the original laceration.** Incise the arms of the Z using a #15 scalpel blade (**Figure 118-1C**). Undermine the flaps of the Z and the surrounding skin. Elevate the flaps of the Z (**Figure 118-1D**). Transpose the flaps so that the wound is reoriented (**Figure 118-1E**). Place simple interrupted sutures to approximate the wound edges (**Figure 118-1F**).

APPROXIMATING THE EDGES OF A LACERATION WITH GROSSLY UNEQUAL LENGTHS

Creating an equilateral triangle from the midpoint of the longest wound edge allows wound edges of unequal length to be closed easily (**Figure 118-2**).³⁻⁵ Determine the widest point between the two wound edges. Determine which of the two wound edges is longer. Mark the middle of the longest wound edge (**Figure 118-2A**). Draw an equilateral triangle centered at this mark (**Figure 118-2B**). **The sides and base of the triangle must all be of equal length and the same length as the widest part of the original wound.** Incise the arms of the equilateral triangle with a #15 scalpel blade and remove the tissue (**Figure 118-2B**). Undermine the wound edges. Close the wound and the perpendicular incision from the triangle with simple interrupted or running sutures (**Figure 118-2C**).

Closure of the two wounds results in a clean linear wound with a short perpendicular linear wound offsetting the previously unequal edges (**Figure 118-2C**).

CLOSING A SQUARE-SHAPED DEFECT

Wounds are rarely square-shaped after an injury (**Figure 118-3A**). Debride the wound to make a square-shaped defect (**Figure 118-3B**). Square-shaped defects can be difficult to close and require a single pedicle advancement flap.³ Elongating two sides of the square allows small and moderate-sized defects to be closed primarily. Draw lines to extend two parallel edges of the square by twice their length (**Figure 118-3C**). Draw Burow's triangles on the ends of the extended lines (**Figure 118-3C**). These triangles will be removed, allowing the flap to be transposed into the wound and creating a more symmetrical flap.³⁻⁵ Draw the Burow's triangles as equilateral triangles whose sides are half the length of the square defect (**Figure 118-3C**).

Incise along the extended lines and Burow's triangles with a #15 scalpel blade. Remove the tissue of the Burow's triangles. Undermine the rectangular flap and the area surrounding the base of the flap. **Do not undermine the area lateral to the extended lines.** Advance the tissue flap to close the defect (**Figure 118-3D**). Place a simple interrupted suture in the center of the short edge of the flap to hold it in position. Place half-buried horizontal mattress sutures to secure the corners of the flap (**Figure 118-3D**). Approximate the wound edges with simple interrupted sutures along the long arms (**Figure 118-3D**). Approximate the corner of the Burow's triangles with half-buried horizontal mattress stitches and the rest of the triangle with simple interrupted sutures.³⁻⁵

FIGURE 118-3. Closure of a square-shaped defect. **A.** The original tissue defect. Draw lines around the defect to form a square. **B.** The skin has been incised and the original defect removed to create a square-shaped defect. **C.** Draw lines to extend two sides of the square into a rectangle. Draw Burow's triangles at the ends of the rectangular lines. **D.** Advance the flap and approximate the wound edges.

FIGURE 118-4. Closure of a diamond- or rhomboid-shaped defect. **A.** The original tissue defect. Draw lines around the defect to form a diamond or rhomboid. **B.** The skin has been incised to create a diamond-shaped defect. Draw lines to form the flap. Extend the short diagonal (BD) by one times its length to form line DE. Draw line EF parallel to line CD and the same length as line CD. **C.** Transpose the flap to close the defect. **D.** Approximate the wound edges. **E.** The four available Limberg flaps that can be created to fill the defect.

CLOSURE OF A DIAMOND-SHAPED DEFECT

Diamond- or rhomboid-shaped defects require the rotation of a flap referred to as a Limberg flap. **The Limberg flap is a transposition flap suitable only for closing a diamond- or rhomboid-shaped defect. It requires the formation of two adjacent angles of the rhomboid that must be 60° and 120° for an optimal flap.**

Wounds are rarely diamond-shaped after an injury (Figure 118-4A). Debride the wound to make a diamond-shaped defect (Figure 118-4A). Draw a line to extend the distance of the short diagonal of the defect to double its total length (Figure 118-4B). Draw a line from the extended line and parallel (back cut) to the adjacent wound edge that is equal to the length of the extended line (Figure 118-4B). Incise along the extended lines with a #15 scalpel blade. Undermine the flap and adjacent skin. Rotate the flap into the diamond-shaped defect (Figure 118-4C). Approximate the wound edges with simple interrupted sutures along the linear edges and half-buried horizontal mattress sutures at the intersection or angles of the wound edges (Figure 118-4D).³⁻⁵ Depending on the location of loose tissue and adjacent structures, one of four Limberg flaps can be created to close the defect (Figure 118-4E).

CLOSURE OF AN ELLIPTICAL DEFECT

Wounds are often irregular and elliptical (Figure 118-5A). Creating an ellipse from a wound allows more even closure of asymmetrical wounds. This is also referred to as an S-plasty. This technique may be used when there is concern of significant scarring and contracture

formation from an associated thermal burn injury and Z-plasties are not recommended.⁴ The less acute and more rounded edges of the ellipse tend to result in less tissue necrosis.^{3,4}

Draw lines to debride the wound and form an S-shaped defect (Figure 118-5A). Incise the extended lines with a #15 scalpel blade to form the S-shaped defect and excise the wound (Figure 118-5B). Undermine the wound edges. Place buried sutures to close the wound and prevent tension on the wound edges. Approximate the wound edges by placing simple interrupted sutures alternating at each end of the S-shaped defect and ending in the middle (Figure 118-5C).

FIGURE 118-5. Closure of an elliptical defect. **A.** The original tissue defect. Draw lines around the defect to form an S-shaped defect. **B.** The skin has been incised and the original defect removed to create an S-shaped defect. **C.** Approximation of the wound edges with simple interrupted sutures.

Suturing from the ends and moving inward reduces the tension on the wound edges.^{3,4}

CLOSURE OF A V-Y ADVANCEMENT FLAP

The V-Y flap is not a rotational flap but rather a V-shaped flap created away from the wound site which then allows the skin to be advanced into the defect (**Figure 118-6**).³⁻⁶ These advancement flaps may be used to avoid defects from lacerations of the fingertips, lips, or face.

Wounds may be oval and elliptical (**Figure 118-6A**). Creating an oval from a wound allows more even closure of asymmetrical wounds. Draw lines to debride the wound and form an oval-shaped defect (**Figure 118-6A**). Incise along the lines with a #15 scalpel blade to form the oval-shaped defect and excise the wound (**Figure 118-6B**). Draw a V-shaped line adjacent to the oval-shaped defect (**Figure 118-6C**). **The line should be the length of the oval-shaped defect and approximately the width of the original wound away from the defect along its entire length.** Although the two sites do not directly communicate with each other, the V-shaped incision allows the original wound to be closed primarily and without tension. Undermine the wound and the V-shaped incision. Approximate the oval-shaped defect with buried sutures, if necessary, and simple interrupted sutures (**Figure 118-6D**). This will result in an opening of the V-shaped defect (**Figure 118-6D**). Draw and incise a line perpendicular to the apex of the V-shaped defect with a #15 scalpel blade (**Figure 118-6E**). The line should be as long as the width of the V-shaped defect. Approximate the three arms of the defect with simple interrupted sutures to form a Y (**Figure 118-6F**).

An alternative V-Y advancement flap can be used to close the injury without making a second wound (**Figure 118-7**). Draw lines to debride the wound and form a V-shaped defect (**Figure 118-7A**). Incise along the lines with a #15 scalpel blade to form the V-shaped defect and excise the wound (**Figure 118-7B**). Draw and incise a line perpendicular to the apex of the V-shaped defect with a #15 scalpel blade (**Figure 118-7C**). The line should be as long as the width of the V-shaped defect. Undermine the V-shaped defect and the perpendicular line. Place a half-buried horizontal mattress suture to close the center of the Y (**Figure 118-7D**). Approximate the edges of the defect with simple interrupted stitches (**Figure 118-7D**).

CLOSURE OF A RECTANGULAR DEFECT

Wounds may be in the form of an ellipse or oblong (**Figure 118-8A**). These can be converted into a rectangular defect to allow primary closure.³ Draw lines to debride the wound and form a rectangular defect (**Figure 118-8A**). Incise along the lines with a #15 scalpel blade to form the rectangular defect and excise the wound (**Figure 118-8B**). Draw lines to convert the short ends of the rectangle into triangles (**Figure 118-8C**). **The width of the rectangle should serve as the measurement to create an equal distance between the base and the apex of the triangle.** Excising triangles from the ends of the rectangular defect reconfigures the ends of the wound. Incise along the lines with a #15 scalpel blade and remove the triangles (**Figure 118-8D**). Undermine the skin surrounding the defect. Approximate the wound edges with simple interrupted sutures to form a straight line (**Figure 118-8E**).

FIGURE 118-6. Closure of a V-Y advancement flap. **A.** The original tissue defect. Draw lines around the defect to form an oval. **B.** The skin has been incised and the original defect removed to form an oval-shaped defect. **C.** Draw a V-shaped line adjacent to the oval defect. It should be positioned the maximum width of the oval defect from the wound edge. **D.** Incise the V and undermine the skin edges. Approximate the oval-shaped defect with buried sutures and simple interrupted sutures. **E.** Draw and incise a line perpendicular to the apex of the V and equal to the maximum width of the V-shaped defect. This forms the V into a Y. **F.** Approximation of the Y-shaped defect.

FIGURE 118-7. An alternative V-Y advancement flap closure. **A.** The original tissue defect. Draw lines around the defect to form a V. **B.** The skin has been incised and the original defect removed to form a V-shaped defect. **C.** Draw and incise a line perpendicular to the apex of the V and equal to the maximum width of the V-shaped incision. **D.** Approximate the center of the Y with a half-buried horizontal mattress suture. Approximate the arms of the Y with simple interrupted sutures.

CLOSURE OF A TRIANGULAR DEFECT (ROTATION FLAP)

Closing of a triangular defect can be accomplished with the use of a rotational flap (Figure 118-9). These flaps can be turned on a pivot point. **The flap must be planned carefully so that the direction of rotation coincides with the geometry of the defect.**³⁻⁵ Always plan and draw the arch of the flap carefully to visualize the pivot point and direction of rotation prior to making the incision. The creation of a rotation flap is a significant procedure. It can result in a vascular disaster and leave a deformity greater than the original defect it was supposed to correct. Do not create a rotation flap unless you have experience with this technique and know that the flap has an adequate vascular supply.

Wounds are often irregular and elliptical (Figure 118-9A). Draw lines to debride the wound and form an isosceles triangular defect (Figure 118-9A). Incise along the lines with a #15 scalpel blade to form the triangular defect and excise the wound (Figure 118-9B). **Draw the rotation flap very carefully.** The edge of the flap is an arch from the base of the triangle and three to four times longer than the actual base of the triangle (Figures 118-9C and 118-9D).³ Draw a second triangle as a Burow's triangle in the area next to the pivot point of the flap (Figure 118-9C).³⁻⁵ **The base of the Burow's triangle should be half the length of the base of the triangular defect, with one corner of the base formed by the end of the arch.** Incise along the lines with a #15 scalpel blade. Remove the Burow's triangle. Undermine the rotation flap and the surrounding skin. Rotate

the flap to close the defect and approximate the wound edges with interrupted sutures (Figure 118-9C). Place half-buried horizontal mattress sutures to approximate the triangular defect and any corners. Place simple interrupted sutures to approximate the remaining wound edges.

A triangular defect may be closed with a modification to the above technique when there is minimal room to form and excise the Burow's triangle or if lines of skin tension limit the location of the pivot point.³ **This modified technique should be considered only when necessary, which may occur from poor planning of the initial flap or in areas where fascia can be separated from the subcutaneous layer (e.g., scalp wounds and areas involving the trunk).**³⁻⁵ Form the triangle to debride the wound and draw the arch as described previously. **Do not draw the area beyond the point perpendicular to the apex of the triangle (Figure 118-9D).** Rather than drawing a Burow's triangle for excision, draw a line to make a back-cut from the pivot point (i.e., the end of the arch) and along the base of the flap (Figure 118-9D).^{3,5} **This line should be three-fourths the length of the base of the triangular defect.** Incise along the lines with a #15 scalpel blade. Undermine the defect and the rotation flap. Rotate the flap to close the defect and approximate the entire wound edge with half-buried horizontal mattress sutures (Figure 118-9D). Suture the back-cut prior to closing the triangular defect or the arch.³ **This alternative technique carries the risk of having a poor blood supply to the flap due to its small base.**

FIGURE 118-8. Closure of a rectangular defect. **A.** The original defect. Draw lines around the defect to form a rectangle. **B.** The skin has been incised and the original defect removed to form a rectangle. **C.** Draw triangles along the short sides of the rectangle. The length from the apex to the base of the triangle must be equal to the width of the rectangle. **D.** The resulting defect after incising and removing the triangles. **E.** Approximation of the wound edges to form a linear scar.

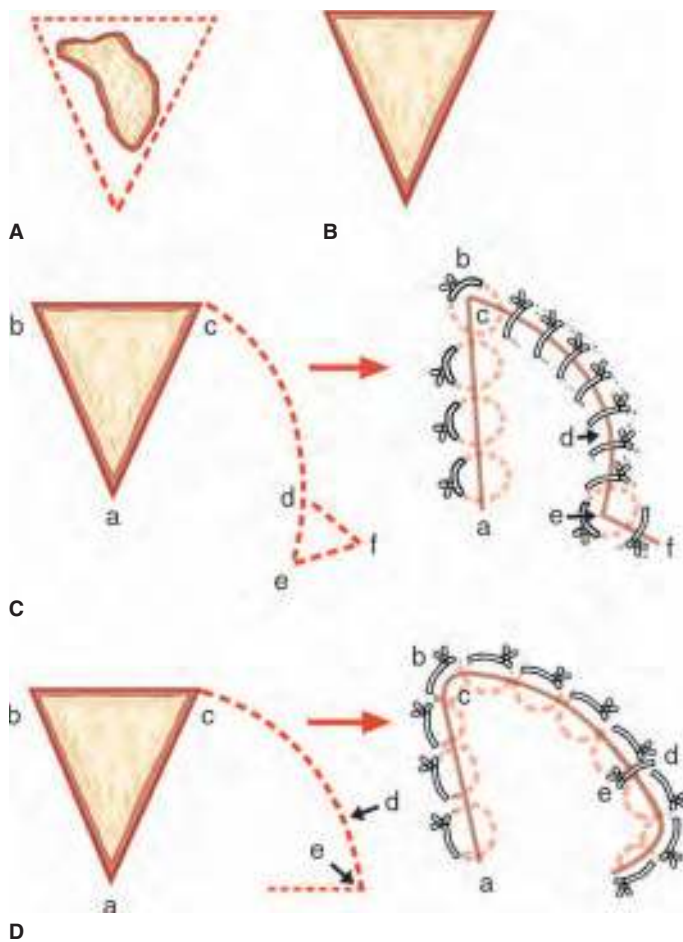

FIGURE 118-9. Closure of a triangular defect. **A.** The original defect. Draw lines around the defect to form a triangle. **B.** The skin has been incised and the original defect removed to form a triangle. **C.** Draw a line to extend the base of the triangle in a wide arc that is three to four times the length of the base of the triangle. Make sure that the arc is drawn beyond the line from point a to point d. Draw a Burow's triangle at the end of the arc. The base of the Burow's triangle should be half the length of the base of the triangular defect. Approximate the triangular defect and any corners with half-buried horizontal mattress sutures. **D.** An alternative technique. Draw a wide arc from the base of the triangle similar to that in C but that ends opposite the apex of the triangle (point a). Draw a line to make a back-cut that is three-fourths the length of the base of the triangular defect. Approximate the entire wound edge with half-buried horizontal mattress sutures.

CLOSURE OF AN OVAL DEFECT

Oval defects can be closed by creating a rotational or interpolation flap from the intact adjacent tissue (**Figure 118-10**).³ Wounds are often irregular and elliptical (**Figure 118-10A**). Choose a side of the oval defect to form the flap. The adjacent skin used to make the flap must be vascularly intact to avoid the risk of tissue necrosis once the flap is sutured into position. Draw lines to debride the wound and form an oval defect (**Figure 118-10A**). Incise along the lines with a #15 scalpel blade to form the oval defect and excise the wound (**Figure 118-10B**). **Draw the rotation flap very carefully. Draw a mirror image of the defect abutting the original wound (Figure 118-10C).** Incise only along the lines noted with a #15 scalpel blade. Undermine the rotation flap and surrounding skin. Rotate the flap to close the defect (**Figure 118-10D**). Approximate the edges of the flap with half-buried horizontal mattress sutures (**Figure 118-10D**). Approximate the wound from where the flap originated with simple interrupted sutures, if it is not excessively large or under tension, or with half-buried horizontal mattress sutures.

CLOSURE OF A CIRCULAR DEFECT

Some defects can be closed primarily. Examples include circular defects or triangular defects that are converted to ellipses (**Figure 118-11**). Excise the tissue defect to form a circle. Excise a surrounding ellipse of tissue centered about the circle (**Figure 118-11A**). **The ellipse must be 2½ to 3 times as long as its greatest width.** Undermine the edges of the ellipse. Close the resulting defect with deep sutures if required and cutaneous sutures (**Figure 118-11B**).

Larger defects require the use of a double V-Y closure (**Figure 118-12**). Draw two sliding pedicle flaps of equal length, one opposite or 180° from each other, and centered about the defect (**Figure 118-12A**). Create the two sliding pedicle flaps with a #15 scalpel blade. **Incise the skin and dermis but not the underlying subcutaneous tissue to form an ellipse centered about the tissue defect (Figure 118-12A).** Remove the tissue defect and debride the tissues at the base of the flaps to form two straight edges (**Figure 118-12A**). Gently undermine the edges of the ellipse. **Do not undermine the triangular tissue flaps so that their vascular supply is preserved.** Slide (i.e., advance) the flaps on their subcutaneous pedicles until the bases are touching. Approximate the base of one flap to the other using simple

interrupted sutures (**Figure 118-12B**). Approximate the arms and bases of the Ys using simple interrupted sutures.

ASSESSMENT

Inspect the wound edges carefully for adequate approximation. Observe the wound for a period of time to make sure that it remains viable and is not compromised due to a poor blood supply or tight sutures. **A nonviable repair requires immediate removal of the sutures and consultation with a Plastic Surgeon.**

AFTERCARE

Pull the suture knots lying directly over the wound margin to one side so that all the knots lie on the same side. Wipe off any residual povidone iodine or chlorhexidine solution with sterile saline. Apply

FIGURE 118-12. The double-Y closure to repair a tissue defect. **A.** Create an ellipse centered about the tissue defect. Remove the tissue defect and form straight edges at the bases of the triangular flaps. **B.** Approximate the bases of the triangular flaps, followed by the arms and bases of the “Ys,” using simple interrupted sutures.

a topical antibiotic ointment to the wound followed by a nonadherent dressing. Arrange follow-up in 24 hours with the patient's Primary Care Provider, a Plastic Surgeon, or the Emergency Department. Consider the use of prophylactic antibiotics even though there is no evidence to support or refute this practice.

Instruct the patient and/or their representative regarding wound care and dressing changes. Provide clear instructions of what to look for regarding possible signs of early infection, both localized around the wound site as well as systemic symptoms. Any patient who experiences excessive swelling, erythema, a purulent or foul-smelling discharge, significant pain from the wound site, or fever should return to the Emergency Department immediately.

COMPLICATIONS

A brief discussion of the complications of wound closure is presented below. Refer to Chapter 114 for a more complete discussion. The complications of any wound can be greatly affected by the preparation of the wound prior to wound closure. The maintenance of sterile technique throughout wound closure and adequate irrigation of the wound will limit the risk of infection. It is unrealistic to expect any wound site to be bacteria-free.

Wounds may show poor scar formation or delayed healing due to several factors. Poor aftercare without adequate dressing changes or neglect (e.g., premature exposure to environmental irritants such as dirty water, direct and excessive sun exposure, or chemicals) will likely result in a less favorable and unpredictable healing process. The wound site should be protected from excessive contact or use during the initial healing period. Mechanical trauma or overuse can increase the chance of edema or hematoma formation, leading to wound dehiscence or atypical scar formation.

Proper follow-up should be arranged and stressed within the initial 24 to 48 hours following the treatment and thereafter as may be warranted. Awareness that wound healing takes place in sequential physiologic steps is needed to properly direct patients so that the risk of complications or the need for antibiotics will be minimal.

SUMMARY

Patients present to the Emergency Department with a wide variety of wound types. The use of local flap techniques allows the Emergency Physician to close difficult and complex wounds. If primary closure is not possible, these techniques decrease the tension on a wound and allow for appropriate cosmesis. They require close follow-up and appropriate patient selection if complications are to be prevented.

Management of Specific Soft Tissue Injuries

Thomas M. Kennedy and Christopher Russo

INTRODUCTION

Blunt and penetrating trauma can lead to a myriad of soft tissue injuries. The management of many of these injuries is discussed elsewhere in this text. Some specific soft tissue injuries require detailed explanations for their repair. These injuries are discussed below. Administer immunoprophylaxis (e.g., tetanus and tetanus immune globulin) when indicated. Consider the use of procedural sedation (Chapter 159) in children.

MULTIPLE FOREHEAD LACERATIONS

Forehead lacerations are common in all age groups. They occur most frequently during early childhood. Their location demands a complete head and neck evaluation.¹ **Their visibility requires meticulous attention to detail.** Knowledge of the principles regarding their repair allows for good cosmesis. The repair of forehead lacerations differs from other soft tissue injuries due to the role of skin tension lines, the lack of extra tissue, and scarring promoted by too many deep dermal sutures.²⁻⁴ They are broadly categorized into superficial and deep in relation to involvement of the frontalis muscle.

Forehead injury repair is governed by several principles. Skin tension lines run parallel to the skin creases and play a major role in the outcome of any forehead laceration. Lacerations angled more than 35° from lines of tension are more likely to heal with a poor result.⁵ Consider counteracting skin tension with deep stitches and undermining. Lacerations running perpendicular to skin tension lines are more likely to result in a noticeable scar.^{2,3} There is little excess tissue on the forehead to allow for later wound revisions. **Resist the temptation to excise ragged wounds.**⁴ This leaves enough tissue for the Surgeon to manipulate if further revision is required. **Deep lacerations are closed with a layered repair to maintain muscle function, eliminate dead space, and reduce skin tension. Place as few deep sutures as possible.** They tend to promote more tissue reaction and more noticeable scar formation.

Most forehead lacerations require repair to promote cosmesis and provide hemostasis. The rich blood supply to the area allows primary repair up to 24 hours after the initial insult.¹ This allows referral to a consultant if there is any question about the ability to achieve satisfactory cosmesis or if the wounds are so extensive as to take the Emergency Physician away from their departmental responsibilities for an unacceptably long time. Primary closure beyond 24 hours may be considered after the risk of infection is weighed against the cosmetic benefit and discussed with the patient.¹

Laceration repair is dependent on the type of laceration. Small uncomplicated lacerations and flaps smaller than 5 mm can be closed with 6-0 nonabsorbable suture (e.g., nylon or Prolene) or 6-0 absorbable suture (e.g., fast-absorbing gut) using simple interrupted stitches.¹ Multiple studies in pediatrics have shown absorbable suture to have similar outcomes to nonabsorbable suture in cosmesis and adverse events.⁶ Close larger flaps using the half-buried horizontal mattress stitch. Allow partial-thickness abrasions and gouges less than 1 cm wide and 2 mm deep to heal by secondary intention.^{2,3,7} Bunched up, small flap lacerations can be excised together and the resulting defect repaired primarily.⁷ This technique is described under “Multiple Small Skin Flaps” in this chapter.

Close deeper transverse lacerations that involve the deep fascia or the frontalis muscle in layers with buried stitches using 5-0

absorbable suture (e.g., Monocryl or Vicryl).⁶ Repair the periosteum using 5-0 absorbable suture (e.g., nylon or Prolene).¹ Close the epidermal layer with simple interrupted stitches using 6-0 nonabsorbable suture (e.g., nylon or Prolene) or absorbable suture (e.g., gut), skin closure strips (Chapter 116), or tissue adhesive (Chapter 117). The latter two are attractive alternative techniques of wound closure if the patient is at risk to develop keloids or hypertrophic scars. **Do not use these alternative techniques on vertically oriented lacerations as they are under tension.**⁵ Approximate skin folds, skin creases, and the hairline with great precision.

EYELID LACERATIONS

The objective of eyelid repair is the restoration of normal alignment and anatomic function.⁸ Eyelid lacerations are classified as marginal if they cross the eyelid margin or extramarginal if they do not cross the eyelid margin.⁷ **Consult an Ophthalmologist to close marginal lacerations (Figure 119-1).** Repair requires considerable experience, the use of magnification, and the placement of deep sutures.

Repair of marginal eyelid lacerations demands a thorough understanding of anatomy and a high degree of suspicion for injury to critical structures. The eyelid consists of five layers of tissue (from superficial to deep): skin, subcutaneous tissue, orbicularis oculi muscle, tarsal plate, and conjunctiva. The skin is thin and does not protect the eye from penetrating injuries. The orbicularis oculi muscle controls eyelid closure. The tarsal plate is composed of dense elastic and connective tissue, contains the meibomian glands, and contains the eyelashes.⁹ The levator palpebrae superioris muscle elevates the upper eyelid. Its aponeurosis inserts into the superior tarsal plate and skin of the eyelid. The orbital septum is a membranous sheet that acts as the anterior boundary of the orbit. It extends from the orbital rim, blends with the levator aponeurosis in the upper eyelid, and blends with the tarsal plate in the lower eyelid.¹⁰ On the medial aspect of the eyelids are the superior and inferior lacrimal papillae and puncta which communicate with the canalicular system. The nerve supply to the eyelids arises from the temporal and zygomatic branches of the facial nerve.

A careful history and a thorough physical examination looking for concealed injury or foreign bodies is imperative.^{11,12} The examination must specifically address and exclude canthal injuries, lacrimal apparatus (e.g., most commonly canalicular) injuries, and/or injuries to deep structures. Injuries medial to the lacrimal

FIGURE 119-1. Eyelid laceration involving the margin. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2016. Photo contributor: Lawrence B. Stack, MD.)

punctum must prompt the possibility of a lacrimal apparatus or canalicular injury.¹³ Consult an Ophthalmologist for a probe evaluation and irrigation of the lacrimal apparatus.¹⁴ **Failure to identify canalicular interruptions can compromise outcome.** Canalicular repair delayed beyond several days is less successful than primary repair.¹³ A delay of 2 to 3 days may be advantageous, as the cut medial ends may become edematous, whitened, and easier to locate.^{15,16}

A thorough examination is necessary prior to performing a repair. The assessment should include testing visual acuity, visual fields, extraocular muscles, and for the presence of foreign bodies, globe rupture, and corneal abrasions.⁹ Lacerations that initially appear superficial may be associated with penetration into the eye or intracranial cavity. Carefully evert the eyelid to determine the depth of penetration. Gently pull open one edge of the wound.¹³ Full-thickness lacerations warrant consultation with an Ophthalmologist because improper repair of the inside surface of the eyelid can result in scar formation with persistent corneal irritation.¹⁷ Consider obtaining a computed tomographic scan of the brain, orbits, and midface in these situations to evaluate for a retained foreign body, ruptured globe, or intracranial injury. Ptosis in the presence of an eyelid laceration is concerning for injury to the levator palpebrae muscle or its aponeurosis and requires consultation.¹⁴ Consult an Ophthalmologist for globe rupture, avulsion of eyelid tissue, and marginal lacerations for proper repair to prevent deformity and disability (e.g., ectropion or epiphora). Transmarginal lacerations can be complicated by medial and lateral canthal tendon injury.¹⁸

Recognition and management of injuries to deep structures (e.g., lacrimal apparatus, orbicularis oculi muscle, levator palpebrae muscle, tarsal plates, and medial or lateral canthal tendons) are necessary to prevent dysfunctional tearing, lid malalignment, ptosis, functional abnormalities, and cosmetic defects. Awareness of the eyelid's complex anatomy is essential to the proper recognition and repair of less evident impairment due to injury. Certain key features are reviewed in this section as they are necessary to prevent overlooked injury and understand proper repair.

The eyelid's skin is the thinnest in the body, with that of the upper eyelid being thinner than that of the lower eyelid. The skin moves freely over the deeper tissues and is easily mobilized with forceps. Surface landmarks include, from posterior (nearest the globe) to anterior (nearest the skin), the mucocutaneous junction, the orifices of the meibomian glands, the gray line, and the lash line. **The gray line is a key landmark.** It is located on the palpebral edge and consists of an isolated strip of pretarsal orbicularis oculi muscle just anterior to the tarsus (i.e., Riolan's muscle). Lacerations through the gray line require diligent reapproximation and should be referred to an Ophthalmologist.¹⁹ There are three or four irregular rows containing approximately 100 lashes on the upper eyelid and two or three rows of approximately 50 lashes on the lower eyelid.

The levator palpebrae muscle arises from the roof of the orbit. It inserts into the midtarsus and overlying skin, intimately associating with the orbicularis oculi muscle. Suspect levator injuries with any horizontal laceration of the upper eyelid. Improper repair or failure to repair a laceration may result in ptosis or a deformity of the supratarsal fold.

Canthal injuries must be actively sought. Determine whether the medial or lateral canthal tendon is injured. Apply lateral traction on the eyelid. Displacement of the punctum laterally may be due to a disruption of the medial canthal tendon. Such a disruption is likely to be associated with nasal fractures, orbital fractures, ethmoid fractures, and canalicular injuries.²⁰ Apply medial traction on the eyelid. Displacement of the lateral canthus medially is due to a disruption of the lateral canthal tendon. Inspection and/or probing through the wound may confirm a canalicular interruption. Early repair is

preferred as the tissue becomes more difficult to identify and repair when swollen. The value of early repair of canalicular lacerations is debated.²¹ Early repair may exacerbate the degree of canalicular damage, increase the risk of stenosis, and may result in damage to other parts of the canalicular system.²¹ Consult an Ophthalmologist as meticulous repair is mandatory to avoid damaging the lacrimal apparatus.

The orbicularis oculi muscle closes the eyelids tightly. Failure to properly repair the levator muscle, the tarsal fascia, or the orbicularis muscle in a deep upper eyelid laceration may result in ptosis. Consult an Ophthalmologist for all deep upper eyelid lacerations.

There are at least six published variations on the techniques described for repair of the eyelid margin with less than one-third of tissue loss measured horizontally, yet there is no literature comparing outcomes.^{7,16,17,20,22-24} The experience and skill of the Emergency Physician are vital. Each minor variation aims for precise apposition to avoid malalignment or notching of the eyelid margin. Each technique varies the sequence, number, type, or order of margin stitches (i.e., final or temporary) versus tarsal suture placement and closure (if required).

Eyelid lacerations with tissue loss require individualization.^{15,20} Wound edge loss of less than 25% of the horizontal length of the eyelid can often be closed primarily. Approximate the wound edges with toothed forceps to evaluate wound tension. Freshen (i.e., debride) ragged edges without loss of tissue. **Avoid penetration to the conjunctival surface to avoid contact with the cornea. Accurate repair of the tarsus is vital because it forms the skeleton of the eyelid.** Remove the sutures in 5 days. Tissue loss of greater than 25% may require a canthotomy, cantholysis, or a tissue flap. Refer these injuries to an Ophthalmologist or Oculoplastic Surgeon. Older patients with skin laxity may be able to tolerate a greater than 25% loss with adequate cosmesis.^{15,20}

Some eyelid lacerations without eyelid margin involvement may involve the levator muscle. Evaluate horizontal lacerations of the upper eyelid for levator interruption. Visible fat indicates orbital septum penetration and raises the suspicion of levator involvement (**Figure 119-2**). Repair these lacerations with fine absorbable suture to avoid ptosis.^{19,20} **An eyelid crease and/or minimal levator function suggests an intact levator.**²⁰

The orbital septum lies deep to the orbicularis oculi muscle. The levator palpebrae muscle lies deep to the orbital septum. The septum

FIGURE 119-2. Eyelid laceration with the underlying fat pad protruding. (Used with permission from Schafermayer R, et al: *Strange and Schafermayer's Pediatric Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2015.)

is rigidly attached to the orbit and does not move on traction with forceps. Grasp the levator muscle with forceps and instruct the patient to look up. A brief pull will be felt as the muscle contracts. It is crucial to distinguish between the levator apparatus and the orbital septum. Injuries involving the orbital septum (**Figure 119-2**) carry a higher risk of globe injury, intraorbital foreign body, and orbital cellulitis. **The septum must not be included in a repair of the levator, as it will restrict movement of the levator.** Consult an Ophthalmologist or an Oculoplastic Surgeon for deep extramarginal lacerations with suspected levator muscle involvement. Obtain a computed tomographic scan to evaluate for potential transorbital fascia/septal involvement.²⁵

Complications associated with eyelid repair include malalignment, missed canicular lacerations with attendant tearing dysfunction, missed foreign bodies, corneal abrasions, missed globe injury, missed canthal interruption, and missed fractures with entrapment. Referral of all patients upon discharge from the Emergency Department to an Ophthalmologist or Oculoplastic Surgeon is recommended.

Many lid lacerations can be treated conservatively without sutured repair. Wounds that can be allowed to heal by secondary intention are lacerations that comprise less than 25% of the eyelid and are superficial. A time to primary closure of up to 36 hours is considered acceptable.¹⁴

Repair any laceration that comprises over 25% of the eyelid. Instill a drop of topical anesthetic into the eye followed by a protective sclera shell over the eye to prevent injury.¹³ A Morgan Lens can also be used for this purpose. **Extreme care is needed to avoid deep penetration of the needle into the eye if the laceration is repaired without a scleral shell.**⁸ Administer local subcutaneous anesthetic (e.g., 1% lidocaine with epinephrine) or perform field blocks (e.g., supraorbital, infraorbital, and/or anterior ethmoidal nerve blocks). Perform gentle irrigation. Consult an Ophthalmologist if foreign bodies are unexpectedly encountered and appear to penetrate the globe or orbital tissues. Close the eyelid skin with simple interrupted stitches using 6–0 absorbable suture (e.g., fast-absorbing gut) (**Figure 119-3**).¹³ An alternative is using 6–0 or 7–0 nonabsorbable

suture (e.g., nylon or Prolene) with the plan for removal in 3 to 5 days.²⁰ Take only small bites through the skin layer.⁸ **Do not grasp deep tissue within the eyelid with the suture to prevent an increased vertical tension and ectropion.**²⁶

EAR LACERATIONS

Ear lacerations can result from blunt or sharp trauma to the auricle (**Figure 119-4**).²⁷ The primary goals are to preserve the normal contours of the auricle, to prevent chondritis, and to prevent hematoma formation.^{28,29} The skin of the ear is extremely vascular. **A potential space exists between the auricular cartilage and the adherent perichondrium.** The underlying auricular cartilage is avascular and receives its nourishment from the overlying perichondrium and skin. **Minimize any debridement of the auricular soft tissues to ensure that the repair covers all exposed cartilage.** Auricular laceration repair follows the same principles as other laceration repair techniques. Differences to be appreciated include the importance of debriding as little soft tissue as possible, always covering exposed cartilage, splinting the ear appropriately after the repair, and recognizing the indications for consulting a Plastic Surgeon (e.g., cartilage defects > 5 mm, inability to cover exposed cartilage, devitalized tissue, and complete or near-complete amputations). A subperichondrial hematoma or seroma after repair will cause the cartilage to become infected or necrotic, leading to abscess development or the formation of fibrocartilage causing the deformity (i.e., cauliflower ear).

Examine the area for signs of an acute hematoma or other associated traumatic injuries (e.g., hemotympanum or Battle's sign).¹⁹ Clean, prepare, and anesthetize the auricle (Chapters 156 and 200).³⁰ Consider local infiltration for small and isolated wounds without cartilage involvement or an auricular block for complicated or extensive lesions. **An auricular block is often the best means of providing anesthesia to avoid distortion of the anatomy.** Local infiltration of 1% lidocaine without epinephrine is required if the laceration involves the posterior wall of the external auditory canal or the concha because this area is innervated by the auricular branches of the vagus nerve.¹⁷ Some recommend surgical consultation for lacerations involving the external auditory canal because stenosis of the canal is possible without appropriate management.³⁰ Use only a local anesthetic agent without epinephrine to prevent potential complications. Close simple lacerations primarily with interrupted 6–0 nonabsorbable suture (e.g., nylon or Prolene).

A cotton plug can be inserted into the ear canal during irrigation for patient comfort. **Do not irrigate with such force as to further dissect the cartilage from the perichondrium.**¹⁴ Skin debridement is not recommended in most cases as there is little excess skin available to cover the cartilage.¹⁷ **Close the wound without suturing the cartilage to decrease the infection risk caused by placement of internal sutures if the injury to the cartilage is small and the edges are well opposed.**⁵ Use 6–0 nonabsorbable suture (e.g., nylon or Prolene) in a simple interrupted stitch. Repair the anterior aspect of the auricle first to allow for greater accuracy aligning the more cosmetically important anterior aspect.^{6,14} **Use care to assure all cartilage is covered with skin to prevent the development of chondritis.**²⁷

Close wounds involving soft tissue and cartilage loss of less than 5 mm with a wedge excision and repair technique (**Figure 119-5**).¹⁴ **The auricular skin does not stretch to allow coverage of defects.** The wedge excision technique allows a primary closure that would otherwise have been difficult to achieve without distortion or buckling the anatomy of the auricle due to the underlying cartilage. Debridement performed by the Emergency Physician is controversial. Saving as much tissue as possible is best and leaves more for the surgeon to manipulate if revision is necessary.^{14,17} Consult a Plastic

Surgeon or Otolaryngologist prior to performing any debridement, if possible.

Excise a full-thickness triangle of tissue in the antihelix with a #15 scalpel blade (**Figure 119-5A**).³¹ First mark the area with a surgical marking pen. The angle at the apex should be no more than 30°. Carefully undermine the skin adhering to the cartilage along the wound margins anteriorly and posteriorly, allowing for elevation of the skin off the cartilage to ensure a tension-free closure.³¹ The resultant smooth wound edges can then be closed in a layered fashion after hemostasis has been achieved. **Approximate the skin on the anterolateral surface followed by the posterior surface** with simple interrupted sutures using 6-0 nonabsorbable suture (e.g., nylon or Prolene). **Carefully approximate the ridges and valleys to minimize the cosmetic defect. Place the sutures through the skin and perichondrium and not the cartilage.** The skin and underlying cartilage are so adherent to each other that it is not necessary to close the cartilage separately. A preferred technique by some is to place numerous interrupted sutures through the skin and perichondrium on either side of the wound (**Figure 119-5B**) and then approximate the wound edges by tying the sutures (**Figure 119-5C**).

It is believed that the cartilage fragments will be drawn together and heal much better.

Auricular lacerations can involve one or all layers without any loss of tissue. The cartilage may protrude into the wound further than the overlying skin (**Figure 119-6A**). This type of wound is difficult to close primarily without debridement as the skin does not stretch to cover the cartilage. Use a #15 scalpel blade to carefully trim the cartilage back to the level of the skin or so that the skin overhangs the cartilage by 1 mm (**Figure 119-6B**). This allows the skin edges to be everted when closed. Approximate the skin and perichondrium with simple interrupted sutures using 6-0 nonabsorbable suture (e.g., nylon or Prolene).

Extensive lacerations of the auricle are managed in a similar manner. Trim any protruding cartilage as described above. Place simple interrupted sutures using 6-0 absorbable suture (e.g., Vicryl or Dexon) through the perichondrium to approximate the cartilage at important landmarks and remove tension from the wound edges. Approximate the skin and perichondrium with simple interrupted sutures using 6-0 nonabsorbable suture (e.g., nylon or Prolene).

FIGURE 119-5. The wedge excision and repair technique for auricular lacerations. **A.** Excise a full-thickness triangle of tissue. **B.** Place interrupted nonabsorbable sutures through the skin and perichondrium. **C.** Approximate the wound edges by tying the sutures.

FIGURE 119-6. Repair of an auricular laceration. **A.** The skin has retracted and the cartilage protrudes into the wound. **B.** Trim the cartilage so that it is level with the skin or so that the skin overhangs the cartilage by 1 mm.

Lacerations of the external auditory canal require repair only if the underlying cartilage is exposed. This is done to prevent a chondritis. Pack the external auditory canal with a nonabsorbent wick (e.g., petrolatum gauze wrapped around a cotton ball) to approximate the wound edges and speed the healing process.

Consult a Plastic Surgeon for wounds with tissue loss of greater than 5 mm, wounds with exposed cartilage that cannot be covered without sacrificing greater than 5 mm of cartilage, complete or almost complete ear avulsion injuries, and injuries with devitalization of the auricle. **Care for the avulsed auricle as an “amputated part” to preserve viability should the consultant desire to pursue reimplantation.**

Uncomplicated wounds not involving the auricular cartilage require local wound care and suture removal in 4 to 5 days. Larger wounds and those involving the auricular cartilage require oral antibiotics to cover skin flora and a dressing that conforms to the anatomic configuration of the auricle (Chapter 200). The dressing will provide support and prevent an auricular hematoma from forming. Remove the sutures in 3 to 5 days in children and 4 to 5 days in adults.²⁸ Removal in 7 days has also been advocated.³¹ The decision when to remove the suture is up to the discretion of the Emergency Physician and depends on the clinical situation.

The complications following ear laceration repair are similar to those occurring after all wound repairs. Specific problems include the development of a chondritis, which is much more likely if the auricular cartilage is left exposed. Deformities can be due to the injury itself, poor repair techniques, or the development of an auricular hematoma secondary to poor ear splinting. Antistaphylococcal antibiotic coverage is recommended in cases where cartilage has been exposed or a hematoma has been drained. Recheck drained hematomas in 24 hours to evaluate for reaccumulation.²⁸ Refer to Chapter 200 for a complete discussion of auricular hematoma complications.

NASAL LACERATIONS

The structure of the nose is composed of osseous, cartilaginous, and fibrofatty tissue. Lacerations of the nose are often caused by blunt trauma. Inspection for associated injuries (e.g., facial fractures, cerebrospinal fluid rhinorrhea, or a nasal septal hematoma) is critical. A hematoma can develop between the cartilage and perichondrium of the septum and deprive it of nourishment with consequent septal perforation or saddle-nose deformity.

Important points to note in dealing with nasal lacerations are the extent of the laceration and the structures involved. Cartilage involvement increases the likelihood of developing an infection. Lacerations are difficult to close because the skin is inflexible and lacks redundancy. Associated injuries (e.g., nasal fractures and septal

hematomas) must be managed. Suturing back a totally avulsed nose is unnecessary as it will most often fail.³³

Direct injection of local anesthetic is reasonable for simple lacerations. This can distort the anatomy and be painful. The repair of nasal lacerations requires local anesthesia with an infraorbital nerve block (Chapter 156) or a nasal block (Chapter 203). The nasal mucosa can be anesthetized using cocaine-soaked pledgets (Chapter 203). The location of the injury on the nose determines which nerve blocks are necessary.³⁴ It is safe to use epinephrine-containing anesthetics on the nose.¹⁷ **Significant defects can occur from a small amount of nasal cartilage debridement.¹⁴ Debridement is not recommended.**

Lacerations limited to the outer aspect of the nose (i.e., skin lacerations and not through-and-through lacerations) can be repaired as simple lacerations (Figure 119-7). **Minimize any debridement as the lack of redundancy of nasal skin can result in disfiguring scarring.³⁵**

Lacerations involving the nasal cartilages require a thorough cleansing, minimal if any debridement, and a multilayered closure.³⁶ **Do not place suture through the avascular nasal cartilages as this increases the chances of a postrepair infection.** Approximation of the nasal mucosa, subcutaneous tissues, and skin will oppose the cartilage edges. **It is crucial to have proper alignment of the alar rim and columella to achieve good cosmetic results and to avoid the postrepair complication known as “notching.”³³** The repair proceeds from inside the nose to outward.

The depth of the nasal laceration determines the method of repair.³⁶ Simple, nongaping injuries are straightforward. Repair these with 6-0 nonabsorbable suture (e.g., nylon or Prolene) or 6-0 absorbable suture (e.g., fast-absorbing gut) using simple interrupted stitches. The latter is preferred in pediatric patients. Gaping lacerations require the placement of absorbable subcutaneous suture before skin closure to relieve tension. The skin overlying the nose is taut and sutures can easily tear through the wound edges.^{1,2}

Through-and-through lacerations require layered closure with meticulous alignment of the internal and external alar rim for optimal cosmetic outcome.³⁶ Begin the repair with a 5-0 nonabsorbable suture (e.g., nylon or Prolene) that aligns the skin surrounding the entrance to the nasal canal at the alar margin. Leave the ends of the suture untied and long. Use this suture to apply gentle traction to facilitate alignment of the mucosa and cartilage layers while placing additional sutures.^{4,7} Close the mucosal layer with 5-0 chromic gut suture on a tapered needle with simple interrupted stitches. Suture placement in the cartilage is rarely needed as repair of the overlying skin usually approximates the cartilage. Tie the initial stitch. Close the overlying skin with simple interrupted stitches using 6-0 nonabsorbable suture (e.g., nylon or Prolene), or 6-0 absorbable suture (e.g., fast-absorbing gut), or a continuous subcuticular stitch.^{2,14}

ORAL MUCOSAL LACERATIONS

The two common types of oral mucosal lacerations are those involving the buccal mucosa and those at the mucosal reflections (i.e., labiogingival groove or buccolabial sulcus) located at the transition point between the buccolabial mucosa and the alveolar mucosa.¹⁷ The latter are easily missed without manipulation of the lips to allow proper visualization and their depth can appear deceptively shallow without appropriate wound exploration. Recognizing the presence of any foreign material in the wound (e.g., debris or tooth fragments) remains essential. Inspect the teeth for fractures and consider the need for obtaining a radiograph or bedside ultrasound prior to repairing any wounds.³⁷ Recognizing the possibility of a Stensen duct injury, located adjacent to the upper second molar, is

A

B

C

FIGURE 119-7. Repair of an external nasal laceration. **A.** The laceration. **B.** The laceration 1 day postinjury. **C.** The laceration 7 days postinjury. (Photo courtesy of Benjamin C. Paul, MD.)

critical in the management of a buccal laceration and requires an Oral Surgeon.

Most oral mucosal lacerations are small, heal without intervention, and do not require repair. Wounds requiring repair are those large enough to trap food particles (e.g., greater than 2 to 3 cm) and wounds with a tissue flap that falls between the occlusive surfaces of the teeth.⁶ Consider the age of the wound prior to proceeding with primary repair. Lacerations in the oral cavity more than 6 hours old may be at higher risk for infection.³⁷

Coated 4-0 Vicryl suture on a tapered needle is preferred by some when closing the oral mucosa.^{37,38} Vicryl suture is less irritating to the child and is easier to work with than plain gut suture or chromic gut suture. Tapered needles are less traumatizing to the tissue.^{37,38} Some prefer to place 4-0 silk suture as it is not irritating to the patient and does not tempt the patient to “play” with the suture with their tongue or bite through them. The disadvantage of silk sutures is that they require a return visit for removal. The lacerations can be closed with a continuous stitch or simple interrupted stitch.³⁸

Only include the mucosa in the stitch to prevent an external pucker if the underlying muscle is included.¹⁷ Close through-and-through lacerations of the cheek in layers. Irrigate the injury prior to closure through the external open wound. Leave mucosal injuries open if they are less than 2 cm.³⁸ Close the mucosal layer, if it requires closure, before the muscle and skin. Close the muscle layer and external skin of large flaps.¹⁵ Close the muscle layer first with 5-0 Vicryl suture using simple interrupted stitches and then the skin with simple interrupted stitches using 6-0 nonabsorbable suture (e.g., nylon or Prolene) or absorbable suture (e.g., fast-absorbing gut).

Tissue flaps that fall between the occlusal surfaces of the teeth may be approximated or excised.

The role of prophylactic antibiotics for intraoral lacerations is controversial.³⁹ These wounds are considered contaminated because of the high bacteria count within the mouth.³⁸ Evidence to date is inconclusive regarding the benefit of prophylactic antibiotic therapy. Administration is guided by Emergency Physician discretion. Make the patient aware that it is normal for buccal mucosa lacerations to often develop a white ridge during the healing process and it is not a sign of infection.⁶ A diet of soft foods and liquids is recommended for the first 2 to 3 days after the repair. Rinse the mouth gently two or three times a day and after meals with chlorhexidine solution.

LIP LACERATIONS

The lip has a layered anatomy and requires a layered repair when injured to achieve an optimal cosmetic outcome, maintain proper function, and avoid complications. The skin of the face meets the dry vermilion at the junction between them known as the vermilion border (**Figure 119-8**). This border is further divided into the white line and red line. Its relative pallor compared to the lip and skin makes it easily identifiable.⁶ The dry vermilion is composed of a specialized epithelium that is translucent, allowing the vascular papillae below it to give the lips their pink color.¹⁴ The dry vermilion then transitions into the wet vermilion at the wet-dry junction as the mouth is entered. The wet vermilion is composed of the oral mucosal epithelium. The internal layered structure of the lip from the oral mucosal epithelium to the epithelium of the face is the mucosal

FIGURE 119-8. A lip laceration that crosses the vermilion border. Points “A” and “B” are connected to realign the vermilion border (dotted lines). (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2016. Photo contributor: Kevin J. Knoop, MD, MS.)

epithelium, the submucosa that contains minor salivary glands, inner fibrofatty junction, muscle (i.e., orbicularis oris), outer fibrofatty junction, subcutaneous fat, dermis, and facial epithelium.³⁸ The orbicularis oris muscle has multiple functions including participation in facial expression, speech, and retaining oral secretions.¹⁴

Attention to detail is essential for attaining a good cosmetic result in repairing lip lacerations, as they can result in devastating cosmetic defects if not repaired properly. Malalignment of the vermilion border or the “white line” (i.e., the border between the skin of the face and the red part of the lip) by as little as 0.5 to 1 mm will be easily noticeable.

Lip lacerations can be safely closed primarily within 24 hours of the injury.³⁸ Lacerations presenting beyond this time frame may still be closed after consultation with a Plastic Surgeon as irrigation in the Operating Room or healing by secondary intention may be indicated. **The lips are best anesthetized with regional nerve blocks (Chapter 156 and 209) to not distort the landmarks that demand precise alignment.** This can be accomplished by blocking the infraorbital nerve and mental nerve for upper and lower lip lacerations, respectively. Avoid using epinephrine with anesthesia, as this will blunt the vermilion border landmark.⁴⁰ Inspect the teeth for fractures and explore the wound for foreign bodies. An embedded tooth fragment or other debris can act as a nidus for infection.⁴⁰ A unique aspect of the lip is that any traumatized minor salivary glands should be removed to prevent delayed formation of

a mucocoele.³⁸ **Be sure not to debride any tissue containing the vermilion border.** Irrigate the wound adequately prior to closure.

Discussing the repair of a through-and-through laceration of the lip that includes the vermilion border provides explanations for repair of each layer. The points made are applicable to all less severe lacerations of the lip. Consider debridement of irregular borders.⁴⁰ It is recommended to start the repair of any vermilion border laceration with a tacking stitch and align the red and white lines precisely (Figures 119-8 and 119-9A).^{1,14,17,38} **Misalignment of this border by as little as 1 mm can result in a cosmetically displeasing outcome.**¹⁴ Use 6–0 nonabsorbable suture (e.g., nylon or Prolene). This stitch can be tied immediately or left untied with long tails, which is helpful for through-and-through lacerations (Figure 119-9A). Apply gentle traction on this initial alignment suture when needed to help approximate the underlying tissues as the remainder of the repair is performed. The repair proceeds from the inside out with the oral mucosa first to the wet-dry junction using buried interrupted stitches. Use 5–0 chromic gut suture or coated 4–0 Vicryl suture on a tapered needle. Repair the orbicularis oris muscle to include the inner and outer fibrofatty layers. Use buried interrupted stitches with 4–0 or 5–0 Vicryl suture, plain gut suture, or chromic gut suture (Figure 119-9B). **The muscle must be accurately approximated anteriorly and posteriorly to prevent contraction away from the wound edge and produce a scar with obvious ridging or depression when the lip is in function (i.e., not at rest).**³⁸ Close the dry vermilion and facial skin by placing simple interrupted stitches with 6–0 nonabsorbable suture (e.g., nylon or Prolene) or fast-absorbing gut suture (Figure 119-9C).⁶

The aftercare for a sutured lip laceration is much the same as for oral mucosal lacerations. Instruct the patient to avoid bringing excessive pressure to bear on the suture line. Remove nonabsorbable sutures in 4 to 5 days to avoid scarring. Warn parents that a child may bite the stitches while the lip is still anesthetized and advise them to distract the child from doing so during this time.^{6,40} Administration of prophylactic antibiotics is likely beneficial for through-and-through lip lacerations.^{17,41}

TONGUE LACERATIONS

Most tongue lacerations are the result of oral trauma and tongue biting and usually heal well without intervention (Figure 119-10).⁴² There is controversy associated with the indications for laceration repair of the tongue.¹⁴ Lacerations that do not require repair are generally small, linear, nongaping, and superficial lacerations located in the central tongue region or small flaps on the edge of the tongue that can be excised (Figure 119-10A). Repair full-thickness

Stack, MD.)

lacerations, large lacerations of a free edge, large flaps, lacerations that continue to bleed, those that are likely to entrap food particles, and lacerations that bisect the tongue (**Figure 119-10B**).^{6,14,43} Tongue amputations and large avulsions require microsurgical repair by an Oral Surgeon or an Otolaryngologist.⁴³ The tongue's generous blood supply allows wounds to heal well yet can cause serious hemorrhage and potential airway compromise.^{6,42} Evaluate patients who have tongue lacerations that require repair for potential airway problems, the need for procedural sedation, or the need for general anesthesia.⁴⁰ Some wounds requiring closure can be very challenging to repair.^{2,3,7,44} These may include large lacerations over 1 cm, gaping wounds, actively bleeding lacerations, U-shaped lacerations, wounds that bisect the tongue, and large flaps on the tongue edge (**Figure 119-11**). The main problem is not the repair but achieving control of the area to facilitate the repair.

Anesthetize the tongue via local wound infiltration or a lingual nerve block for the anterior two-thirds of the tongue (Chapter 209). These can be supplemented with procedural sedation techniques

FIGURE 119-11. Repair of a tongue laceration involving the margin. Note the stitch placed at the tip of the tongue to provide control. (Used with permission from Shah BR, et al: *Atlas of Pediatric Emergency Medicine*, 2nd ed. New York: McGraw-Hill; 2013.)

(Chapter 159). Keep the mouth open during the repair by using a bite block, padded tongue depressor, or a Denhardt-Dingman side mouth gag.⁶ Instruct an assistant to gain control of the tongue. Grasp the anesthetized tip of the tongue with a towel clip, a suture through the tip of the tongue, or a gauze square (**Figure 119-11**).³⁸ Thoroughly irrigate the wound. Close the laceration using absorbable 4-0 plain gut, chromic gut, or Vicryl sutures. Take large bites that include the mucosal and muscular layers of the tongue. Take full-thickness bites to include the two mucosal surfaces and the muscle between or half-thickness bites with one suture from above and another from below.⁴³ **Buried or deep sutures are not required when taking large bites.** Multiple well-secured sutures are preferred to prevent the untying of suture material with tongue motion.⁴² An alternative is inverted sutures tied loosely to prevent untying or tearing of the muscle fibers as the tongue swells.^{6,43} Tissue adhesive may be used in the future to close tongue lacerations.⁴⁵

The infection rate of tongue lacerations is low. Some recommend that all patients be discharged home with a prescription to use an antibiotic mouthwash (e.g., chlorhexidine gluconate 0.12%) twice per day for 1 week.^{14,43} Extensive complex tongue lacerations are at a greater risk for infection and should be treated with prophylactic antibiotics that cover normal oropharyngeal flora.⁴² Children with tongue lacerations may chew off the stitches. Inform parents of this and instruct them to distract the child until the local anesthesia wears off.⁴⁰ After-care instructions are similar to those for oral mucosal lacerations.

GINGIVAL LACERATIONS

Gingival lacerations differ from other anatomic sites in that there is often no subcutaneous tissue available to anchor the flap. Small gingival lacerations tend to heal well without intervention because of the extensive blood supply in this area. Repair wounds that are large, actively bleeding, gaping open, or that fall onto the occlusive surface of the teeth.

Flaps retract after injury and initially appear too small to cover the wound. They give the appearance of an avulsion. However, the flap can usually be spread to cover the wound.⁴⁶ A topical anesthetic (e.g., 20% benzocaine) can be used prior to primary repair. Alternatively, perform a regional nerve block (Chapters 156 and 209). The anterior maxillary gingiva as far posterior as the maxillary molars can be anesthetized by performing a regional block of the infraorbital nerve.⁴⁷

FIGURE 119-12. Gingival laceration repair. **A.** Front view. **B.** Superior view.

Flap lacerations of the teeth (i.e., gingival degloving) expose the alveolar ridge and tooth roots pose a special problem, as there is no subcutaneous support to anchor the mucosa. A flossing technique can be performed using 4-0 or 5-0 chromic gut or Vicryl suture to hold the flap in place.⁴⁶ The suture can be passed between the teeth or the needle can be passed through the gingiva. The technique requires the placement of a 4-0 or 5-0 absorbable suture that first runs circumferentially around and then is tied posterior to the tooth.⁴⁸ Place the suture 2 to 3 mm proximal to the gingival margin (**Figure 119-12A**). Place the suture through the gingiva so that it passes circumferentially around the tooth to secure the flap (**Figure 119-12B**). Loosely tie the suture on the inner aspect of the tooth so that the knot does not irritate the lip or strangle the tissues (**Figure 119-4B**). The aftercare is the same as described under “Tongue Lacerations” in this chapter. Consider a prescription for an antibiotic mouthwash (e.g., chlorhexidine gluconate 0.12%) twice per day for 1 week.^{43,46}

SUTURING THROUGH HAIR

It is inadvisable to shave hair bordering the edges of a laceration, as this only serves to increase the likelihood of a wound infection.^{47,49} Instead of shaving the hair, brush it aside or mat it down using petroleum jelly or antibiotic ointment prior to wound repair. **It is important to never to shave eyebrows or eyelashes as they will take months to grow back.**⁵⁰ Always debride an eyebrow laceration oblique to the hair follicles and not perpendicular to the skin edge (**Figure 119-13**). This will reduce the loss of hair follicles and prevent ingrown hairs.

MUSCLE LACERATIONS

The repair of muscle lacerations begins with a careful assessment of the extent of injury and the level of contamination prior to repair. Large and/or grossly contaminated muscle injuries require

FIGURE 119-13. Repair of eyebrow lacerations. **A.** Debride the wound edges obliquely and parallel to the hair follicles and not perpendicular to the wound edges. **B.** Approximate the wound edges.

operative management. All other muscle injuries may be managed in the Emergency Department. Treatment should focus on repair or reconstruction of a muscle using its long tendons of origin and insertion to anchor the repair, as the muscle tissue alone is inadequate for suture repair.⁵¹

Lacerations of the fascia surrounding a muscle are common. Thoroughly cleanse the area and debride any devitalized tissue. Approximate small violations of the muscle fascia with simple interrupted stitches using 3-0 or 4-0 absorbable suture (e.g., Vicryl or Dexon). Closing small rents will prevent symptomatic herniation of muscle tissue through them in the future. Do not repair large violations of the muscle fascia. Anecdotal reports of muscle compression and compartment syndromes after such repairs abound.

Lacerations through the muscle require a thorough cleansing and debridement of any devitalized tissue. Repair the laceration with 3-0 or 4-0 absorbable sutures (e.g., Vicryl or Dexon). **Place modified horizontal mattress stitches similar to repairing an extensor tendon (Chapter 96) to close the laceration in a muscle.** Interrupted sutures are not effective, as they tend to pull through the muscle fibers and not hold.

INCOMPLETE LACERATIONS

Incomplete lacerations involve the epidermal and superficial papillary layers of the skin but spare the deep papillary layer. Excise the loose epidermal pieces of skin. Cover the wound with petrolatum gauze and a pressure dressing. The wound can heal by second intention. Alternatively, use Steri-Strips (Chapter 116) or tissue adhesive (Chapter 117) to close the laceration.

WOUNDS OF UNEQUAL THICKNESS

Wounds of unequal thickness are not suited for repair with simple interrupted sutures. Unequal tissue loss on each edge of a wound creates a thick edge–thin edge wound. **The depressed edge must be elevated to the level of the nondepressed edge to attain proper wound apposition and cosmesis.**

There are two techniques to repair wounds with edges of unequal thickness. The first technique uses a half-buried horizontal mattress stitch (**Figure 119-14**).^{1,3} Place the suture through the thick edge of the wound, across the wound and buried into the subcutaneous tissue of the thin edge, and back out the skin of the thick edge (**Figure 119-14A**). Apply traction to the suture and tie it to approximate the wound (**Figure 119-14B**). Apply an ointment-based compressive dressing.

The second technique requires undermining both wound edges at the same depth in the subcutaneous tissue plane (**Figure 119-15**).⁷ Make an incision in the subcutaneous tissues of both wound edges and at the same level (**Figure 119-15A**). Undermine the area to free

FIGURE 119-14. Closing a wound with edges of unequal thickness using half-buried horizontal mattress stitches.

FIGURE 119-15. An alternative technique to close a wound with edges of unequal thickness. **A.** Make an incision in the subcutaneous tissue of both wound edges. **B.** Undermine the edges. Transpose the subcutaneous tissue of the thicker side into the undermined area of the thinner side (arrow). **C.** Approximate the wound edges using interrupted sutures.

the tissue flaps (**Figure 119-15B**). Grasp the subcutaneous tissue flap from the thicker side and insert it under the thinner side beneath the undermined area (**Figures 119-15B and 119-15C**). Place a buried horizontal mattress stitch to maintain the flaps in position. This “flap” elevates the depressed wound edge and facilitates appropriate wound approximation (**Figure 119-15C**).⁷ Place interrupted sutures to approximate the wound edges (**Figure 119-7C**).

Tangential flap lacerations over thin skin (e.g., the dorsum of the hand or the pretibial area) where there is very little subcutaneous tissue can be approximated with a specially placed simple interrupted suture. Insert the needle through the tip of the thin edge, across the wound, into the dermis of the thick edge, and out the skin of the thick edge. Apply traction to the suture to pull the thick edge up to meet the thin edge, producing good approximation rather than overlap of the edges. Tie the sutures to oppose the wound. Apply an ointment-based compressive dressing.

An alternative technique uses Steri-Strips to strengthen the skin so the suture does not pull through the thin skin. Apply benzoin to the intact skin on both edges of the laceration. Do not get the benzoin in the wound. Allow 1 to 2 minutes for the benzoin solution to dry and become tacky. Place stitches through the skin and Steri-Strips.

FLAP LACERATIONS

Flap lacerations occur when shearing forces to the skin tear the dermis from the underlying subcutaneous tissues. This type of laceration is problematic because the flap is separated from its blood supply except for the blood entering through the base. This makes

the flap susceptible to necrosis and infection. A flap will remain viable if the base of the flap is three times its length.⁵³ Flaps with a ratio of less than 3:1 are less likely to survive intact.

A flap can easily be repaired primarily if it has viable edges and meets or exceeds the 3:1 ratio of base to length. Anesthetize, clean, and prepare the area. Trim the excess fatty tissue from the underside of the flap. This will improve the chances of healing. Place a half-buried horizontal mattress stitch to close the corner or the tip of the flap (**Figure 119-16C**). Approximate the sides of the flap with simple interrupted sutures or half-buried mattress stitches (**Figure 119-16C**).

Some viable flaps have nonviable edges that must be debrided prior to closure to ensure proper cosmesis and survival of the tissue. Debride the nonviable edges sharply with a #15 scalpel blade or an iris scissors (**Figures 119-16A and 119-16B**). Place a half-buried horizontal mattress stitch to close the corner (**Figure 119-16C**). This is necessary to close the flap and relieve pressure. Approximate the sides of the flap with simple interrupted sutures, mattress stitches, or half-buried mattress stitches (**Figure 119-16C**).

Some flaps may be too small after debridement or be under too much tension to stretch across the wound. These flaps can be closed by forming a Y-shaped closure instead of a V-shaped closure (**Figure 119-16C**). Place a half-buried horizontal mattress stitch to close the tip of the flap. Approximate the base and arms of the Y with interrupted sutures, mattress stitches, or half-buried mattress sutures.

A flap laceration may present difficulties. It may not be possible to revise and repair it, or it may be nonviable. It is often possible to

FIGURE 119-16. Repair of a flap laceration. **A.** Sharply debride the edges. **B.** The resultant defect. **C.** Approximation of the wound edges. First place a half-buried horizontal mattress stitch to close the tip of the flap. Approximate the remaining wound edges with interrupted sutures.

FIGURE 119-17. Closure of a tissue defect. **A.** Excise the defect and a surrounding ellipse. **B.** Approximation of the wound edges with deep and cutaneous stitches.

“ellipse” the flap (**Figure 119-17**). Excise the tissue defect to form a circle. Excise a surrounding ellipse of tissue centered about the circle (**Figures 119-17A and 119-17B**). The ellipse must be $2\frac{1}{2}$ to 3 times as long as its greatest width. Undermine the edges of the ellipse. Approximate the center of the resulting defect using a locked vertical mattress stitch, which allows approximation of the remainder of the wound with minimal extrinsic tension. Approximate the remainder of the resulting defect with deep sutures, if required, and cutaneous sutures (**Figure 119-17B**).

There is not enough tissue in some cases to cover the defect no matter what technique is attempted. These wounds may be left to heal by secondary intention if small or referred to a Plastic Surgeon for skin grafting. The only complication unique to the repair of flap lacerations is the possibility that the flap may not survive and require referral, revision, or skin grafting.

AVULSION INJURIES

The treatment of tissue avulsion injuries varies depending on the amount of tissue lost and its depth. Allow full-thickness defects less than 1 to 2 cm² to heal by secondary intention after debridement. Full-thickness defects greater than 2 cm² require a different approach using skin grafts or flaps or converting the wound to one that can be closed primarily. Treat avulsed tissue as an “amputated part” that may be used in the repair process. Consider consulting a Plastic Surgeon for a large avulsion that cannot be closed primarily or to convert it into a wound that can be closed primarily.

Some defects can be closed primarily. Examples include circular defects or triangular defects that are converted to ellipses (**Figure 119-17**).³ This technique is described above under “Flap Lacerations.”

Larger defects require the use of a double V-Y closure. This converts the flap to a different shape prior to the repair and thus increases the chances of successful primary closure (**Figure 119-18**).³ Create two sliding pedicle flaps with a #15 scalpel blade. **Incise the skin and dermis but not the underlying subcutaneous tissue to form an ellipse centered about the tissue defect (Figure 119-18A).** Remove the tissue defect and debride the tissues at the base of the flaps to form two straight edges (**Figure 119-18A**). Gently undermine the edges of the ellipse. **Do not undermine the triangular tissue flaps so their vascular supply is preserved.** Slide (i.e., advance) the flaps on their subcutaneous pedicles until the bases are touching (**Figure 119-18B**). Approximate the base of one flap to the other

FIGURE 119-18. The double V-Y closure to repair a tissue defect. **A.** Create an ellipse centered about the tissue defect. Remove the tissue defect and form straight edges at the bases of the triangular flaps. **B.** Approximate the bases of the triangular flaps followed by the arms and bases of the Y's using interrupted stitches.

using simple interrupted stitches using nonabsorbable suture (e.g., nylon or Prolene) (**Figure 119-18B**). Approximate the arms and bases of the Y using simple interrupted stitches using nonabsorbable suture (e.g., nylon or Prolene).

MULTIPLE SMALL SKIN FLAPS

Numerous small skin flaps that are bunched up, as commonly seen when a patient's forehead shatters a windshield, are difficult to repair individually. Excise them as a group to form a single laceration that can be repaired primarily (**Figure 119-19**). Larger and more “spread out” groups of flap lacerations can be repaired in a manner similar to that described under “Multiple Forehead Lacerations,” above.

DISTAL FINGERTIP AMPUTATIONS

Injuries of the distal fingertip rank among the most frequently injured parts of the hand.⁵⁴ Amputations of the fingertip are defined as loss of the tissues distal to the insertions of the extrinsic flexor

FIGURE 119-19. Repair of multiple small lacerations. Excise the lacerations as a group to form a single wound that can be closed primarily.

FIGURE 119-20. Fingertip amputations. **A.** Volar angulation without bone exposure. **B.** Volar angulation with bone exposure. **C.** Transverse or perpendicular angulation with bone exposure. **D.** Dorsal angulation with bone exposure. and extensor tendons on the distal phalanx, distal to the level of the lunula. These injuries may include skin, pulp, bone, the nail matrix, and/or the nail plate (**Figure 119-20**).⁵⁴ Multiple classification systems to describe the pattern of injury and facilitate communication have been developed (e.g., Allen, Fassler, and Tamai classification schemes).⁵⁵ The Allen classification is based on the transverse level of amputation. The Fassler system is based on the geometry of pulp loss and whether there is exposed bone. The Tamai classification system better defines vascular injury and facilitates treatment planning. Anatomic classification schemes for the level of injury are multiple and make literature comparisons problematic. It is best to describe injuries related to anatomic landmarks.

The goals of managing fingertip amputations include optimizing healing time and cosmesis, preserving sensory function and length, limiting nail deformity, and minimizing time lost from work.⁵⁶ Treatment options have evolved remarkably over the past 30 years, although change in clinical practice has lagged. Multiple treatment modalities exist and depend on whether the amputated part was retrieved, its condition, the character of the injury, the patient's preference and underlying health status, availability of consultants, and sophistication of consultants. Current recommendation is to place the amputated part in saline-moistened gauze in a bag that is kept cool in an ice-water mixture.⁵⁷

Perform a physical examination of the injured finger. Obtain radiographs of the finger and the amputated part. Perform a digital block (Chapter 156). Obtain a bloodless field by applying a digital tourniquet. Thoroughly irrigate the wound and debride any devitalized tissue.

Amputations with pad loss of less than 1 cm, with and without bone exposure, can be treated with conservative nonsurgical management with serial dressing changes of nonadherent gauze (**Figures 119-21 and 119-22**).⁵⁸ A petrolatum gauze dressing is best used to cover the wound. It is effective at optimizing healing and minimizing discomfort when removed.⁵⁷ Attempt to place this dressing only on the wound itself to avoid maceration of the intact skin. Cover this dressing with standard gauze. Instruct the patient to soak the wound in warm water mixed with antibacterial soap daily for 10 minutes followed by irrigation with tap water and reapplication of petrolatum gauze dressing covered with gauze for the first 10 to 15 days.⁵⁹ Apply a finger splint for protection. Advise the patient to follow-up with a Hand Surgeon within 48 hours.

Nonoperative open management has been shown to be at least as effective as primary closure, local and distant tissue-transfer flap procedures, and grafts.⁵⁹⁻⁶⁸ Conservative management is advocated

FIGURE 119-21. A fingertip degloving. (Photo courtesy of www.lifeinthefastlane.com.)

in children less than 12 years of age, as they have greater regenerative potential than adults.^{54,69}

Amputations proximal to the lunula are less common. Those who address the issue specifically recommend shortening and primary closure without discussion or data. These injuries require emergent consultation for possible reimplantation. Injuries from the flexor digitorum profundus insertion to approximately the level of the mid-nail can be replanted if the amputated part is available.⁷⁰⁻⁷² The purpose of replantation is the restoration of cosmesis and function. The patient's perception may be that replantation will restore functional and cosmetic normality. Inform the patient that this is doubtful. Consultation with a Hand Surgeon is recommended for all patients with a complete amputation proximal to the lunula to determine if replantation is indicated.⁵⁹

Conservative therapy usually provides acceptable preservation of contour, better salvage of two-point discrimination than grafts, is cheaper than replantation, is associated with a virtual absence of postsurgical infections, and limits joint stiffness. It is equivalent to other techniques in terms of functional use, preservation of length, and time absent from work. Eventual patient satisfaction may be even greater than with surgical techniques. Patients may have to be convinced that closure by secondary intention is both rational and optimal. A set of photographs demonstrating this is often helpful.

FIGURE 119-22. A fingertip amputation. (Photo courtesy of www.lifeinthefastlane.com.)

Clean, prep, and anesthetize the finger. Apply a tourniquet if not done previously. Fingertip amputations tend to bleed profusely. Achieve hemostasis with direct pressure using a nonadherent dressing while the hand is raised above heart level for several minutes. Do not remove the dressing if this is successful. Consider the application of a sterile compression sponge covered with a nonadherent dressing and the application of pressure if the bleeding continues. Attempts at cauterizing bleeding vessels are usually unsuccessful because of the tissue's vascularity.

The presence of protruding bone poses several treatment options. Some physicians rongeur any protruding bone exposure less than 0.5 cm in length with soft tissue loss of less than 1 cm² until it is flush with the wound surface and thereafter continue open treatment.⁵⁹ There is no published evidence supporting rongeur of protruding bone in adults. Anecdotal statements supporting this technique exist in texts.^{62,68} Published reports support not shortening protruding bone in children under the age of 12.^{66,73} Healing may be prolonged if protruding bone is not debrided or if it is debrided later. Consider trimming the nail bed back to the bone margin if a remnant overhangs or is not supported by adequate bone.

Dress the wound with either a bulky hand dressing or tube gauze and a disposable splint (e.g., metal or plastic).⁷⁴ The use of prophylactic antibiotics is controversial in fingertip amputations, including those with open fractures.^{57,75} Consider antibiotics in contaminated wounds or those with significantly devitalized tissue. Refer all patients to a Hand Surgeon or primary care provider in 24 to 48 hours. Inform all patients of the 30% to 50% incidence of sensory impairment (e.g., diminished sensation, cold intolerance, dysesthesia), impaired function, or cosmetic deformity.^{61,63,67,68,76}

Document this discussion in the medical record. Additional indications for consultation with a Hand Surgeon include specific occupational concerns or when the thumb or index finger is affected.⁵⁹ The possibility of a wound infection is very small with conservative treatment.⁶⁵

ANIMAL BITES

Approximately 1% of annual Emergency Department visits in the United States are for the management of bite wounds.⁷⁷ These bites are from dogs (80% to 90%), cats (5% to 10%), humans (2% or 3%), and rodents (2% to 3%).^{78,79} A thorough understanding of the management of these injuries is essential. The goals of management include identification of injuries to underlying structures (e.g., tendon, bone, vasculature or joint space), retained foreign bodies (e.g., teeth), signs of infection, appropriate irrigation and debridement

of devitalized tissue, determination of primary versus secondary closure, and administration of prophylactic therapies for infection (e.g., local bacterial infection, tetanus, rabies, hepatitis, syphilis, and HIV).

Obtain plain radiographs if there is concern for a fracture, joint space violation, or retained foreign body. Any injury to tendons or vasculature requires appropriate surgical consultation. A bite wound of the dorsal hand (e.g., clenched fist injury) may cause a tendon injury that may not be visible in the wound field when the fingers are extended. **Examine all hand wounds through a full range of motion of the fingers for tendon injury or penetration of the joint capsule.**⁸⁰ Pain with finger motion is suspicious for a deep compartmental infection or tendonitis.⁷⁹

Signs of local wound infection warrant immediate initiation of antibiotic therapy. The microbiology of wound infections from bites is directly related to the oral flora of the offending species. The most common bacteria involved in dog and cat bites include *Staphylococcus*, *Streptococcus*, and *Pasteurella*.⁸¹ *Pasteurella multocida*, found most commonly in cat bite wounds, can cause a wound infection within hours of injury. An important pathogen is *Capnocytophaga canimorsus*, which can cause fulminant sepsis in immunocompromised patients bitten by dogs. Primary closure of bite wounds is avoided in patients with immunodeficiencies.⁸² Human bite wounds are usually infected by *Staphylococcus*, *Streptococcus*, and *Eikenella*.⁸³ Patients with systemic symptoms warrant hospitalization for intravenous antibiotic therapy.⁷⁹ Appropriate treatment is with ampicillin-sulbactam or clindamycin plus a fluoroquinolone, if penicillin allergic, for adults and clindamycin plus trimethoprim-sulfamethoxazole for children.⁸³

The importance of proper local wound care with irrigation and debridement cannot be overemphasized. It prevents infection more effectively than prophylactic antibiotics.⁷⁹ **Copiously irrigate the wound. Antibiotic coverage is no substitute for meticulous wound cleansing. Debridement of devitalized tissue decreases infection risk.**⁸⁴ Cleaning the wound with soap and water will decrease the transmission rate for rabies.⁸⁰ The infection rate is further decreased 20-fold by irrigating with sufficient pressure by using a 19 gauge needle or angiocatheter attached to a 30 mL syringe.⁷⁹

Determining whether to close the wound primarily is based on numerous factors (Table 119-1). **Wounds at high risk for infection should not be closed primarily. These include wounds sustained by a cat or human bite, puncture wounds, wounds < 2 cm in size, hand and foot wounds, wounds more than 12 hours old, and wounds in immunosuppressed patients.**⁷⁹ Do not close wounds less than 2 cm in size in cosmetically insignificant areas. They can

be closed with delayed primary closure or allowed to heal by secondary intention. An exception to this general rule is cat and human bite wounds on the face and neck.^{5,82} The excellent vasculature supply and the importance of an optimal cosmetic outcome in these areas may outweigh the risk of infection. Primary closure of dog bites resulted in a similar infection rate to unclosed bites but better cosmesis.⁸⁵ Primary closure of a human bite wound to the face is associated with an infection rate of approximately 10%.⁸⁵ Have a thorough discussion with the patient regarding this risk and document this discussion in the medical record. Some experts suggest closing the subcutaneous dead space of large hand wounds with a minimal amount of absorbable stitches and closing the skin 3 to 5 days later if there is no evidence of infection.⁷⁹ **Limit the use of buried sutures as they can increase the infection rate of a repaired bite wound.**

Determining whether to administer prophylactic antibiotics is based on numerous factors (Table 119-2).⁷⁷ The data demonstrating their effectiveness for bite wounds are limited. A Cochrane review suggests that prophylactic antibiotics significantly decrease the risk of infection after primary closure in hand wounds sustained by dog and human bites.⁸⁶ The review did not include studies on hand injuries from cat bites. It found no benefit of prophylactic antibiotics for wounds sustained to other areas of the body. Wounds sustained from cat bites have a higher rate of infection than those sustained by dog and human bites likely due to the deeper penetration of bacteria resulting from their long and thin teeth. Human bites have a higher rate of infection than dog bites. Experts recommend prophylactic antibiotics for all cat and human bite wounds.^{77,79,82} Prophylactic antibiotics are indicated for bites more than 8 hours old with significant crush injury or edema or potential damage to adjacent structures (e.g., bones, joints, or tendons), for deep puncture wounds, in older patients, in immunocompromised patients, and for bites near or in a prosthetic joint.^{79,83} Administer the first dose intravenously to obtain effective tissue levels rapidly followed by an oral course.⁸³ Bite wounds not involving a joint or tendon can be cleaned, debrided, splinted, watched expectantly on an outpatient basis, and treated with oral antibiotics.⁸⁷ Instruct the patient to keep the hand elevated and return in 12 to 24 hours for a reevaluation.

Treatment time depends on structures involved.⁸⁸ Treat for 5 to 7 days if a tendon or joint is involved. Treat for 3 to 5 days if a tendon or joint is not involved. Antibiotics include amoxicillin-clavulanate (875 mg orally twice daily), doxycycline (100 mg orally twice daily), moxifloxacin (400 mg orally or intravenously [IV] once daily), ampicillin-sulbactam (3 gm IV four times daily), or imipenem (1 gm IV four times daily).

Dress bite wounds allowed to heal by secondary intention with a nonadherent dressing (e.g., petrolatum gauze) to maintain a moist environment for epithelial regeneration.⁸² Immobilize extremities with extensive wounds. Apply bulky mitten dressings and support the hand with an arm sling.⁷⁹ **Always consider the need for immunoprophylaxis for tetanus, rabies, viral hepatitis, syphilis, and**

HIV. Consult the local public health department for guidelines and the incidence of rabies in your community.

The discharge instructions are just as important as the Emergency Department management. Provide the patient with a written copy of a wound care sheet, regardless of whether the wound was closed primarily. Instruct the patient to elevate any involved extremity, even with antibiotic treatment.⁸⁹ Arrange follow-up within 24 to 48 hours for a reevaluation of the wound. Physical therapy following a hand infection may be required and initiated 3 to 5 days after any infection resolves.⁹⁰

DEBRIDEMENT OF GUNSHOT WOUNDS

The lack of primary literature on this subject makes it a controversial area. Wounds created by low-velocity bullets tend to cause damage only along the bullet track. Debridement is unnecessary for wounds created by bullets with muzzle energy of less than 400 foot-pounds, as many consider bullets to be sterile.⁹¹ Devitalized and contaminated tissue is more likely to result from shotgun wounds and high-velocity bullets.⁹² The shock wave created by the bullet damages tissue distant from the track of the bullet.⁹² Consider these wounds for debridement.⁹² The debridement of gunshot wounds requires exposure of the entire bullet track and treatment as a delayed closure followed by referral for skin grafting if needed.

Clean, prep, and anesthetize the skin overlying the path of the bullet or shotgun blast for tangential and superficial wounds. Consult a surgeon for other wounds as they need to be debrided in the Operating Room. Incise the wound with a #11 scalpel blade to expose the area. Sharply debride any devitalized and contaminated tissue. Cover the wound and refer the patient to a surgeon for follow-up. Repeat staged exploration at 24 hours and 48 hours to remove necrotic or devitalized tissues.⁹³ Treat the patient with prophylactic antibiotics.⁹³ Consider delayed closure techniques, giving priority to reestablishment of bony relationships followed by soft tissue coverage.⁹³ Consider skin grafting for large areas of tissue destruction for adequate closure.

ABRASIONS

An abrasion is a skin wound created by tangential trauma to the epidermis and dermis. The skin is forced against an abrasive surface in a rubbing fashion and the resultant injury resembles a thermal burn. The goals of managing an abrasion include the prevention of infection, promotion of healing, and prevention of "tattooing" with retained foreign bodies. Large and heavily contaminated abrasions are best managed in the Operating Room. The volume of local anesthetic required to achieve anesthesia would likely exceed toxic limits.

Prepare the wound. Anesthesia may be required prior to wound management. EMLA cream, which contains lidocaine and prilocaine, produces anesthesia of the intact skin but must be in place for about 60 minutes to provide significant benefit.⁹⁴ Perform a field block or regional nerve block (Chapter 156) as appropriate. Large abrasions may be anesthetized by applying 5% lidocaine gel topically for 5 to 10 minutes. Remove any dirt or debris using a sterile scrub brush and surgical soap or saline. Consider radiographic imaging to evaluate for potential foreign bodies.⁴⁰ Use the tip of a #11 scalpel blade to remove deeply embedded and larger particles from the wound. Apply petroleum jelly or antibiotic ointment to remove embedded tar.⁹⁵ Apply an antibacterial ointment to the wound and a dressing.

Instruct the patient to cleanse the wound three to four times a day. Cover the wound with petrolatum gauze and sterile gauze. Instruct the patient on how to properly cleanse the wound and reapply the bandage. Provide the patient with wound care supplies prior to discharge from the Emergency Department.

Subcutaneous Foreign Body Identification and Removal

David Murray, Laura Chun, and Dhara P. Amin

INTRODUCTION

Wounds with a retained foreign body (FB) are a frequent presenting complaint to Emergency Departments. It is important to identify and remove debris and FBs to promote optimal healing. **The presence of a FB may not be obvious.** Up to 38% of embedded objects are missed on the initial assessment and many of these are frequently missed because imaging was not performed at that time.¹ **The presence of an unrecognized FB can lead to infection, joint injury, loss of function, osteomyelitis, pain, tendon rupture, tenosynovitis, and vascular injury.**²⁻⁷ Chronic FBs may lead to the formation of pyogenic granulomas.⁸ Certain soft tissue FBs have the capacity to migrate great distances months to years after the original injury, leading to increased morbidity and mortality from what originally was a benign FB.⁹ **Assess patients presenting with chronic, recurrent, or delayed skin infections for the presence of an unrecognized FB. Failure to diagnose and treat a FB is a common cause of litigation against Emergency Physicians. A high index of suspicion and careful methodical examination, including appropriate imaging, must be undertaken to identify a FB.**

It is important to be familiar with the characteristics of different types of FBs because they may have various pathologic consequences. This information is crucial in determining the urgency or necessity for removal, the imaging techniques required to identify the object, the approach to removal, and determination of whether specialty referral is needed. **The successful removal of a FB requires a directed history and physical examination, appropriate imaging, adequate light, anesthesia, exposure, hemostasis, proper equipment, and patient cooperation. The removal of FBs from subcutaneous tissue can be a frustrating and time-consuming endeavor. The Emergency Physician will need to dedicate a reasonable uninterrupted time to attempt removal, provide wound care, and assure appropriate follow-up.**

It is important to note that a new type of self-injury known as self-embedding behavior has recently been described in adults and adolescents.¹⁰ It involves the self-insertion of a FB into soft tissues. This behavior is relatively rare and is usually not a suicide attempt. Patients who self-embed most often have behavioral health diagnoses. This behavior indicates a much higher risk for this population to commit accidental or intentional suicide.¹¹ **It is the responsibility**

of the Emergency Physician to treat the injury and to provide appropriate referral for prompt psychiatric evaluation.

ANATOMY AND PATHOPHYSIOLOGY

Only a small percentage of wounds contain concealed FBs.¹² The mechanism of injury may give some idea of the likelihood of a retained object.¹ Crush wounds and puncture wounds, especially those involving the sole of the foot, as well as wounds deeper than 5 mm involving adipose tissue, are associated with a higher incidence of FBs that are often difficult to find.¹² Motor vehicle accidents have a higher incidence of retained FBs compared to other injuries.¹³ Wounds caused by objects that shatter, splinter, or break in the process have a higher risk of a retained FB.⁹ **Glass is the most commonly found retained FB.**^{9,14} Lip or facial lacerations associated with dental fractures must be explored for pieces of teeth. Thorns, spines, or splinters tend to penetrate deeply and break. Broken-off needles are common FBs in injection drug users. Objects greater than 4.5 mm in diameter that penetrate the skin may push fragments of epidermis deep into the wound, producing an epidermal inclusion cyst, which can act as a FB.¹⁵

Depending on the type of material retained and the physical form of the foreign object, excess inflammation may delay healing or destroy surrounding soft tissues. Wood, thorns, spines, and other organic FBs are considered highly inflammatory and can lead to chronic granulomatous reactions, osteolytic lesions, periosteal reactions, or severe infections (e.g., necrotizing fasciitis).¹⁵⁻¹⁷ The presence of soil in wounds markedly lowers the concentration of bacteria required to cause an infection by its interaction and interference with white blood cells.¹⁸ Wounds tend to be resistant to antibiotics when a FB is present and it may be impossible to eradicate the infection until the FB is removed.^{2,3,19} Glass, metal, and plastic are relatively inert materials.²⁰ Metals that oxidize may cause mild to moderate inflammation. Some retained FBs (e.g., lead) have the potential to produce systemic effects when in contact with pleural, peritoneal, cerebrospinal, or joint fluid.¹⁸ Retained FBs that are not dissolved or extruded by the body's defenses become encapsulated, after which the inflammation will subside.²¹

HISTORICAL AND PHYSICAL ASSESSMENT

Patients presenting after an injury require a focused history including the details of the incident, the wounding agent, and the mechanism of injury. This information may suggest the presence of a retained FB and direct which imaging study is required.^{22,23} Patients presenting with a FB sensation are more likely to have FBs identified on exploration or with imaging. **Using the patient complaint as a sole determinant would miss most FBs.**¹³ Accurate diagnosis may be made more challenging. A history of skin puncture is often not recognized or reported by the patient.²⁴ Historical features (e.g., diabetes, immunosuppression, lymphedema, peripheral vascular disease, or renal failure) may cause difficult wound management and healing.²⁵ Assess past anesthetic history and the potential for aspiration if procedural sedation is to be considered.²⁶ Review the patient's medications, allergies, and tetanus immunization status. Provide booster doses and/or tetanus immunoglobulin as indicated.

A directed physical examination should begin with a brief inspection and documentation of the distal neurovascular status and function. Consider vascular injuries and address them before continuing with the rest of the examination. An injured extremity must be carefully examined through a full range of motion to ensure the integrity of the tendons. Discoloration of the skin may suggest a FB.¹⁵ Palpation may reveal superficial FBs. Sharp localized pain with palpation over a puncture wound may suggest a retained FB. Adequate

anesthesia, lighting, and good hemostasis are required to allow a thorough examination of the wound. **The examiner must avoid probing only superficially since the subcutaneous tissue can reapproximate and give the appearance of a superficial wound.** Extend the wound edges with a scalpel to facilitate inspection if there is concern regarding a retained FB and direct visualization is difficult.

A retained FB can be ruled out with a negative predictive value of 96% for wounds less than 5 mm deep if the bottom of the wound is visible.¹² **Never insert a gloved finger to probe the wound cavity. This can result in injury from sharp FBs.** Gentle blind probing with a hemostat is an acceptable and preferred alternative. A grating sensation that can be appreciated by the examiner is produced if the probe strikes a metallic or glass FB. **Avoid blind grasping within a wound with a hemostat.** Direct visualization is preferable when examining wounds of the face, feet, or hands.

RADIOLOGIC ASSESSMENT

Imaging is indicated in most cases where a retained FB is suspected but not found during wound exploration, when thorough exploration of the entire wound cavity is not possible, if the mechanism suggests a higher risk for retained FB, or if the patient feels that there is a retained FB. An Emergency Physician should have a low threshold for using appropriate diagnostic imaging while understanding the limitations of each of these tools (Table 120-1).

PLAIN RADIOGRAPHY

Most FBs missed during the initial clinical examination can be seen on plain radiographs.^{16,27} Plain radiographs are readily available. Some authors suggest radiographic evaluation of nearly any penetrating wound involving an extremity.^{1,4,28} Digital radiography has been proven superior to plain film radiography for the detection of subcutaneous FBs.²⁹ Perform standard anteroposterior and lateral radiographs using an underpenetrated "soft tissue technique" to increase the contrast between the FB and the surrounding tissue.³ Oblique and other views can be added to avoid superimposition of the object over bony structures. Visibility of foreign material in soft tissues is dependent upon its composition, configuration, orientation, relative density, and size.^{30,31} Radiopacity should not be considered an all-or-nothing concept. The radiographic appearance of a FB depends on its characteristics and the characteristics of the surrounding tissues. Certain FBs may be visible radiographically in one part of the body but not another.³² The terms "radiopaque" and "radiolucent" will be used to describe the characteristic radiographic appearance when visualized within the subcutaneous tissues. Aluminum, bone, certain plastics, gravel, metal, pencil graphite, sand, and teeth are routinely visible on plain radiographs.^{3,31,33} **Glass fragments were once thought to require lead or heavy metal to be visible on radiographs. Glass fragments as small as 0.5 mm appear on two-view plain radiographs if not obscured by bone; fragments of glass as small as 2 mm appear in the presence of overlying bone regardless of lead content.**^{34,35}

TABLE 120-1 Comparison of Radiology Tests of Foreign Bodies

FB	Plain Radiograph	US Scan	CT Scan	MRI Scan
Glass	Good	Good	Good	Good
Metal	Good	Good	Good	Poor due to interference
Organic material	Poor	Good	Good	Good
Plastic	Moderate	Good	Good	Good
Wood	Poor	Good	Good	Good

Organic materials and plastics are not reliably detected on plain radiographs. They may be indirectly shown as a radiolucent filling defect when the object is less dense than the surrounding tissue, making plain radiography worthwhile even in cases of suspected nonradiopaque FBs.^{36,37} This allows consideration of radiographs while understanding this imaging modality's poor overall sensitivity in these situations.

Examine the entire radiograph for the appearance and location of any FBs.³⁸ Other imaging modalities are required if there is a strong suspicion of a retained FB that usually does not show up on plain radiographs.

The advantages of plain radiographs include their universal availability, low cost, and familiarity to most Emergency Physicians. The disadvantages include the inability to resolve objects with densities similar to body tissues and poor sensitivity for detecting organic matter. Plain films do not demonstrate anatomic structures that may be intervening between the skin and FB along the planned surgical approach. It may be difficult to accurately judge the depth of a FB using two-dimensional radiographs.¹⁵ Standard radiographs remain a clinically practical screening modality for FBs despite these drawbacks.³⁰

ULTRASOUND (US)

Radiography alone is not sufficient to identify a nonradiopaque FB. Bedside US should be the next diagnostic tool to be considered. US can help determine the depth, size, shape, and relationship of the FB to nearby structures.^{39,40} These factors may influence the timing and technique of attempted extraction while potentially preventing the patient from being exposed to additional radiation.⁴¹ The lack of radiation and its ease of use dictates an assessment with bedside US as a screening tool when FBs are suspected or not found on plain radiography.

Studies have shown ultrasonography to have a higher sensitivity for radiolucent FBs than plain radiography.^{42,43} **High-resolution real-time US using a 7.5 MHz or greater linear array transducer can detect radiolucent superficial FBs with a similar radiographic density as the surrounding tissue.** It should be the first choice in the imaging of suspected radiolucent FBs.^{15,44-48} This includes fish bones, sea urchin spines, small glass fragments, vegetative material, and wood.^{15,48-52} Wood FBs can cause severe inflammatory reactions and act as a source for infection. They should be evaluated with US

in patients in whom radiographs are negative.⁴⁹ This is especially important in the Emergency Department where wood FBs make up as much as 34% of all FBs and plain radiographs have a sensitivity as low as 7.4% for organic material.⁵⁰ One study showed that the accuracy of detection of radiolucent objects was above 80% when performed by US Technologists, Radiologists, and Emergency Physicians.⁵²

US can localize a FB within three dimensions. This can help to establish its relation to adjacent bone, muscle, tendons, and tendon sheaths.⁴⁶ Preoperative US results in less damage to the surrounding tissues, reduced operative time, and reduced postoperative morbidity.^{46,53}

The procedure for locating a subcutaneous FB with US begins with selecting the highest available transducer frequency.⁵⁴ Higher frequency transducers have better resolution for superficial structures. The use of a standoff pad or gel-filled glove with the air and talc carefully removed can act as a dead zone for objects that would normally be too superficial to fall within the focal zone of the transducer (**Figure 120-1A**).⁵⁵⁻⁵⁷ The water-basin technique can be used in a similar manner. Place the wounded extremity in a basin of water and align the transducer above the skin (**Figure 120-1B**).⁵⁸ Adjust the focus to the required depth and proceed to scan the field in two orthogonal planes.⁵⁴ Refer to Chapter 121 for more details regarding US-guided FB identification and removal.

The US appearance of FBs is related to the surface characteristics and not its composition.^{59,60} Metals and needles are often hyperechoic with reverberation artifact or comet tails. Gravel is usually hyperechoic and shows dense posterior acoustic shadowing. Organic materials have a characteristic appearance and are ideal for US evaluation. Wood is most often hyperechoic with a posterior acoustic shadow (**Figure 120-2**). Wood FBs lose echogenicity over time.⁶¹ Furthermore, FBs are often surrounded by a hypoechoic halo (**Figures 120-3 and 120-4**).^{35,37,51} This frequently represents a zone of edema, granulation tissue, or abscess formation.⁵² The hypoechoic halo can represent an inflammatory response and may not be visible for the first 24 hours.⁴⁹ Doppler US may reveal a hypoechoic or black ring around a hyperechoic or white FB. Doppler shows marked hyperemia around the periphery of a FB which is considered a reliable secondary sign.⁶² It has been hypothesized that injection of saline into the interstitial space around a suspected FB may make bedside US more sensitive. A cadaveric study failed to show a significant improvement.⁶³

A

B

FIGURE 120-1. US identification of superficial FBs. **A.** A glove used as a stand-off pad. (Used with permission from reference 57.) **B.** A water bath. (Used with permission from reference 58.)

FIGURE 120-2. An US image of a subcutaneous thorn. The FB is hyperechoic (white) with an acoustic shadow deep to it.

Mark both ends of the FB on the patient once a FB has been located on US.⁶⁴ This can be done by inserting paper clips between the skin and the transducer and connecting both ends with a marked dotted line. **Meticulously scan along the entire length of the suspected FB and visualize the FB perpendicular to the transducer.**

There are several disadvantages when using US, including the level of skill required for its use in diagnosing musculoskeletal FBs.^{53-56,58-65} Studies assessing the accuracy of US have shown a sensitivity of 30% to 100% and a specificity of 70% to 90%.⁶⁶ These values have been mostly demonstrated in referred patients studied by Radiologists and certified technicians.^{67,68} US performed by Emergency Physicians has a limited specificity ranging from 47% to 59% under conditions that replicate a typical Emergency Department situation.⁶⁸⁻⁷⁰ Small wood FBs 1 cm or less in size may fail to be identified by bedside US, further limiting its utility.⁶⁶ Another disadvantage is that false positives can occur with air in wounds, calcifications, fresh bleeding, keratin plugs, old scar tissue, ossified cartilage, sesamoid bones, sutures, and tendons.^{15,49,56} Prior exploration for FBs will place patients at higher risk of having false-positive findings from scar tissue.⁷¹ US localization may be difficult if the object is close to bone or deep to subcutaneous gas.⁵⁹ **A high suspicion for a retained subcutaneous FB not identified by bedside US should follow with a request for a formal diagnostic imaging study.**

FIGURE 120-3. An US image of several shards of glass in the palm. Note the hyperechoic (white) FBs surrounded by an echo-poor (black) signal consistent with either a hematoma or edema.

FIGURE 120-4. US-guided removal of a wooden splinter using crocodile forceps. The echogenic jaws of the forceps are seen grasping the FB. The hypoechoic “halo” around the splinter is demonstrated. (Image courtesy of Dr. Mike Bradley.)

COMPUTED TOMOGRAPHY (CT) SCAN

Consider CT imaging in cases where radiography and US have failed to demonstrate suspected FBs (e.g., radiolucent material or objects that cannot technically be located due to overlying bone or gas).⁷²⁻⁷⁵ CT is sensitive in differentiating densities and can detect more types of FBs.^{22,76-79} It is helpful for high-risk wounds when there is potential for infection or joint involvement. CT images can be created in multiple planes and can demonstrate the relationship of a FB to anatomic structures.^{76,80} Three-dimensional reconstruction images are accurate in identification of complex FBs and their associated complications.⁸¹ CT-guided percutaneous placement of a catheter or needle can guide surgical dissection to a FB and aid in the subsequent removal.^{76,80,81} The disadvantages of CT scanning include its higher cost, radiation dosage, availability, and the need for patient cooperation. Organic FBs become less visible over time due to absorption of body fluids.⁴²

MAGNETIC RESONANCE IMAGING (MRI)

MRI imaging may be considered for chronic or complicated FBs.⁴¹ MRI appears to be more accurate than any other modality for identifying wood, glass, plastic, spines, and thorns.^{22,76} It is superior to CT scanning in detecting the presence and extent of edema, hemorrhage, or infection surrounding FBs.^{22,76} MRI's other advantages include the high resolution and contrast between adjacent tissues. It allows the precise localization of FBs in three dimensions to aid in surgical planning and assessment of the need for advanced exploration, debridement, and irrigation. MRI does not expose the patient to radiation.⁸² Magnetic resonance angiography (MRA) is the diagnostic modality of choice when there is clinical suspicion of a FB associated with vascular injury.⁴¹

The disadvantages of MRI include its lack of availability and high cost. Patients must be assessed to rule out a magnetic FB due to the risk of movement of the FB during MRI scanning.⁸³ Prior history of an ocular or other metallic FBs must be sought prior to MRI scanning to prevent iatrogenic injury. This requires a thorough screening history and plain radiographs prior to MRI scanning. Gravel and ferromagnetic substances produce significant artifact so that differentiating scar tissue, tendons, and calcifications from an actual FB can be challenging.^{22,84}

INDICATIONS

Make every effort to identify FBs, even if they are not likely to be removed. It must be decided whether an identified FB needs to be removed immediately, electively, or if at all (**Table 120-2**). Factors that influence the decision to proceed with attempted removal include the size and reactivity of the FB, its proximity to vital

TABLE 120-2 The Indications for Removal of a FB

Allergic reaction
Chemically reactive
Contaminated wounds (e.g., feces, saliva, or soil)
Cosmesis
Heavy metals
Impairs gait
Impinging on structures (e.g., nerves, tendons, or vessels)
Infection in area
Intraarticular
Intravascular
Migration potential
Persistent pain
Proximity to fractured bone
Psychological stress of patient
Vegetative material
Venomous spines

structures, and associated injuries. These must be weighed against the potential for further tissue damage and contaminating the wound. An extraction attempt will depend on the amount of time an Emergency Physician can safely allocate while providing appropriate care to the other patients in the department. Superficial FBs in adults can be removed using local anesthesia. Pediatric FBs may be removed in the Emergency Department under procedural sedation or in the Operating Room under general anesthesia. Consider delaying the removal of deep-seated FBs in adults as the procedure will be more successful in the Operating Room.⁸⁵

A FB requires urgent removal if it is likely to provoke significant tissue inflammation or injury.^{3,86,87} Immediately remove contaminated objects (e.g., FBs located in the presence of an established infection, soil, and teeth).^{3,18} Immediately remove allergenic FBs, those causing hemorrhage, those causing ischemia, or toxic FBs.^{3,87} Remove FBs having the potential for migration, interfering with motor function, or interfering with sensory function.³ FBs in the hands and feet usually require removal as they may cause persistent pain and have the potential to sever nerves or tendons.⁵ The FB may require removal for cosmetic or psychological reasons.¹

CONTRAINDICATIONS

A FB should be urgently removed under ideal operative conditions by an appropriate Surgeon if it is associated with a neurovascular injury or is located near blood vessels, nerves, or tendons.^{1,3} Avoid deep exploration of the hands and feet to prevent injuring intricate structures. Large, deep, and impaled FBs are assumed to help tamponade an active hemorrhage and should be left in place until removed in the Operating Room.³⁸ FBs associated with fractures or located within a joint require prompt surgical debridement to prevent osteomyelitis or septic arthritis.⁸⁷ Urgent surgical intervention is required for all high-pressure injection injuries. These injuries may initially appear innocuous but often cause extensive damage and carry a significantly high risk of complications.⁸⁷ Consider referral based on experience, anticipated problems related to the FB's location or depth of penetration, the duration of retention, or other patient factors likely to complicate the procedure or follow-up.

A deeply embedded, inert object not near any vital structure can be left in place. The difficulty of removal is usually not worth the potential tissue damage. These patients can be referred for elective removal if necessary.^{1,87} **The patient must be informed and possible complications must be discussed if the decision is made not to remove a FB. This includes migration of the FB and infection. Document this discussion in the medical record.**

EQUIPMENT

- 18 gauge needles
- 27 gauge needles
- 10 mL syringes
- Povidone iodine or chlorhexidine solution
- Lidocaine with and without epinephrine
- Topical 4% liposomal lidocaine
- Depilatory wax, rubber cement, or hardening facial gel
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Nylon suture, 1-0 or 2-0
- Methylene blue
- Paper clips
- Wire grid
- Eye magnet
- Hemoclips
- Hemoclip applier
- Fluoroscopy unit
- Hemostats, two sizes
- Forceps, Crocodile and Mosquito
- Sharp scissors
- 22 gauge needles for localization
- Magnification eye loupes
- Normal saline
- 19 gauge blunt-tip needle or angiocatheter
- 35 mL syringe
- Blood pressure cuff or Penrose drains
- 4×4 gauze squares
- Adhesive tape
- Bedside US with high-frequency transducer
- Standoff pad, gel-filled glove, or small basin of water

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. FB removal can be frustrating and time consuming, even when performed under ideal conditions. It is appropriate to set a time limit that is reasonable based on the staffing and volume of the Emergency Department. Inform the patient of the planned time limit at the outset. The search should be discontinued and the patient referred to a Surgeon after expiration of the predetermined time.

Apply povidone iodine or chlorhexidine to the skin site surrounding the wound. Avoid spilling the solution into the wound cavity as both are toxic to wound defenses and may increase the incidence of a subsequent wound infection.¹⁹ Obtain a bloodless field to adequately examine a wound for a FB. Place a blood pressure cuff proximal to the injury. Elevate the extremity for at least 1 minute and then inflate the cuff to a pressure greater than the patient's systolic blood pressure. This is safe for up to 2 hours but will cause some discomfort.⁸⁸ A local vasoconstrictor can be used with the anesthetic to control localized capillary bleeding if no contraindications exist. A 0.25 to 0.50 inch Penrose drain can be wrapped tightly around a finger or toe and secured in place with a hemostat.

An alternative method for achieving hemostasis of a finger involves cutting out a “finger” from a glove. A cut is made across the tip of the “finger.” Place the cut finger from the glove on the affected finger. Roll the latex finger from distal to proximal to create a “ring tourniquet” at the base of the proximal phalanx. Consider using Trendelenburg position for removing FBs in the foot. Elevation above the level of the heart can easily be achieved by placing the patient in a steep Trendelenburg position. This position can vastly reduce bleeding at the site of incision without the use of a tourniquet.⁸⁹

Adequate anesthesia is crucial to the procedure. A field block or regional nerve block (Chapter 156) does not distort the wound.⁹⁰ Consider using topical anesthetics (Chapter 154) in the pediatric population. Liposomal lidocaine has a very fast onset and is associated with higher success rates, reduced procedure time, and less pain.^{91,92} Procedural sedation (Chapter 159) or general anesthesia may be required if cooperation is not possible.

TECHNIQUES

SUPERFICIAL WOOD OR ORGANIC SPLINTER REMOVAL

Very fine FBs can be difficult to visualize. One method to help localize them is to spread soft soap very lightly over the skin.⁹³ Only superficial organic splinters and FBs should be pulled out with forceps as they often come apart and leave a fragment that is more difficult to remove.^{3,94} Cactus spines or wood splinters occasionally lie superficial and parallel to the skin surface. Make an incision parallel to the long axis of the FB and then lift it out of the wound. Enlarge the skin entrance wound with a scalpel so that the FB can be grasped and withdrawn with a hemostat under direct visualization if it is lodged in the subcutaneous tissue. The splinter can be removed by picking it out with an 18 gauge needle, using light feathering strokes to de-roof the skin over the splinter. Subungual splinters may be removed using a “V-cut,” in which sharp scissors are used to remove a V-shaped piece of nail to visualize the underlying splinter and remove it using forceps (Chapter 128). **Caution must be exercised not to disturb the nail matrix for more proximal subungual splinters because this may result in failure of the nail to grow back normally.**²⁰

Small cactus spines may be difficult to locate and remove directly. Application of a depilatory wax, rubber cement, or a water-soluble facial gel with a brush can successfully aid in the removal of small fine spines.⁸⁶ Apply the wax, rubber cement, or facial gel over the skin containing the protruding spines. Apply a layer of gauze over the wet substance. Allow the substance to dry onto the skin and the gauze. Remove the gauze to lift off the dried substance and attached spines. Repeat this process as required to remove the remaining spines.

FIGURE 120-5. Creating an ellipse to remove a contaminated or embedded FB. **A.** An ellipse is made in the skin surrounding the FB. **B.** The epidermis is removed to expose the FB. A block of subcutaneous tissue (dotted line) can be removed if the FB is difficult to visualize. **C.** The skin, the subcutaneous tissue, and the FB can be removed en bloc.

PUNCTURE WOUNDS

Puncture wounds of the foot are commonly seen in Emergency Departments. Punctures not infrequently drive pieces of clothing, shoes, or other debris deep into the wound and result in an infection rate of approximately 10%.⁹⁵⁻⁹⁷ Puncture wounds in the distal foot may profit from debridement and irrigation.

Puncture wounds can be trimmed or ellipsed to remove contaminated and/or embedded FBs (**Figure 120-5**).³ This technique works well for FBs that are difficult to localize. Make an ellipse in the skin surrounding the FB with a #15 scalpel blade (**Figure 120-5A**). Lift the ellipse of skin and separate it from the underlying dermis (**Figure 120-5B**). The FB may be visible. Grasp it with hemostats or forceps and remove it from the tissue.

The FB and the ellipsed puncture wound can both be extracted in a block of tissue if unable to exactly localize the object (**Figure 120-5B, dotted line**).⁹⁰ **First ensure that no blood vessels, nerves, or tendons will be injured.** Alternatively, make the skin ellipse and extract the block of tissue containing the FB without dissecting the skin from the subcutaneous tissue (**Figure 120-5C**). Both techniques allow for the removal of FBs and better cleaning of the wound. Puncture wounds of the foot require careful follow-up due to the risk of infection.

There are several alternative techniques if removing an ellipse of skin and/or tissue is contraindicated or if the Emergency Physician is not comfortable with this technique (**Figures 120-6 and 120-7**). A FB may be embedded perpendicular to the skin (**Figure 120-6A**). Make a linear incision that passes 1 mm to the side of the puncture wound with a #15 scalpel blade (**Figures 120-6A and 120-6B**). Spread the incision open. Visualize the FB (**Figure 120-6C**), grasp it with a hemostat, and remove it.

Another technique involves making a superficial skin incision and manually expressing the FB (**Figure 120-7**). Make an elliptical incision surrounding the FB or a linear incision over the FB (**Figure 120-7A**). Remove the ellipse of skin or spread the linear incision. Undermine the subcutaneous tissues surrounding the FB (**Figure 120-7B**). Apply digital pressure over the undermined areas to displace the FB into the center of the wound and upward (**Figure 120-7B**). Grasp the FB with a hemostat and remove it.

GEOMETRIC APPROACH FOR A NEEDLE IN THE FOOT

A technique that is useful for the removal of a needle in the plantar surface of the foot involves the use of standard anterior, posterior, and lateral radiographs to identify the cutaneous site corresponding to the location of the needle.⁹⁸ The incision site is determined by bisecting the midpoint of the needle, as seen in each projection, by a line drawn at right angles to the long axis of the needle. The ideal plane of dissection is perpendicular to the needle's midpoint, which is correlated with the surface anatomy of the foot.

FIGURE 120-6. Removal of a FB embedded perpendicular to the skin. **A.** The embedded FB. The dotted line represents the proposed incision line. **B.** A linear incision is made 1 mm lateral to the FB. **C.** The incision is spread open to visualize and remove the FB.

Prepare and anesthetize the skin after determining the dissection plane. Make a 0.5 to 1.0 cm skin incision in the plane perpendicular to the needle in its midpoint. Advance an iris scissors into the incision and along the dissection plane with the blades slightly open. Advance the scissors 1 to 2 mm and close the blades. Withdraw the scissors slightly. Open the blades of the scissors, advance them 1 to 2 mm, and close the blades. **Care must be taken to avoid cutting the flexor tendons, although they are located deep and in close association to the bones of the foot.** Continue this process of advancing and closing the blades until the needle prevents closure of the scissors. Advance a hemostat into the wound and over the blades of the scissors. Grasp and secure the needle. Pull the hemostat out of the wound to simply back the needle out of its entry tract. This procedure is reported to have a 100% success rate and takes approximately 10 minutes.⁹⁸

DYE TECHNIQUE FOR LOCALIZING A NEEDLE

Methylene blue may be used to track the location of a FB.⁹⁹ After identification of a FB by plain radiography or US, clean and prepare the skin. Sterilely inject 0.1 to 0.2 mL of methylene blue very gently through the entrance wound of the FB. The dye will travel along the path of least resistance, that is, the path of the FB. Make an A-, U-, V-, or Y-shaped incision from the point of entry and raise a flap of tissue. The blue dot of dye may serve as a guide to the location of the FB. This procedure is often complicated by seepage of the dye and is of limited value.

FIGURE 120-7. An alternative technique to remove a FB from a puncture wound. **A.** Incise and remove an ellipse of epidermis (1). Alternatively, make a linear incision centered over the FB (2). **B.** Undermine the subcutaneous tissue surrounding the FB. Apply digital pressure (arrows) to visualize and express the FB.

NYLON SUTURE TECHNIQUE

One technique described for use in fresh wounds involves the localization of a FB by marking its entry tract with a nylon suture.¹⁰⁰ Grasp a piece of 1-0 or 2-0 nylon suture between the thumb and index finger. Rotate the suture while pushing it into the wound so that it follows the tract made by the FB. It is reported that the FB is easily felt when the nylon contacts the FB.¹⁰¹ Leave the suture in the wound tract. Open the wound tract by cutting alongside the nylon suture until the FB is reached, at which time it is removed. A 92% success rate up to 48 hours after the time of injury has been reported with this technique.¹⁰⁰

PAPER CLIP X-RAY LOCALIZATION

Simple paper clips may be used to locate a FB (**Figure 120-8**).^{101,102} Obtain plain radiographs to demonstrate the presence of a radiopaque FB. Bend two or more paper clips into different shapes. Place the ends over the wound entry site. Secure the paper clips in position with tape. Obtain two plain radiographs or an US taken at right angles to each other. Examine the radiographs or US to determine the cutaneous location of the FB in relation to the paper clips and note its depth from the skin surface. Mark the exact cutaneous location of the FB on the patient's skin with a permanent ink pen. Remove the paper clips.

Clean, prepare, and anesthetize the skin. Make a stab incision at a 90° angle to the middle of the FB, taking the shortest distance between the skin and the FB and following the method discussed for the geometric approach for a needle in the foot. Insert a small hemostat into the incision. Advance the hemostat allowing localization of the object with minimal probing. Grasp and remove the FB.

TAGGED HEMOCLIPS

Even with the most elaborate marking system using grids or needles, it can be difficult to find FBs once the dissection begins since the tissues may be distorted by retraction, edema, or local anesthesia. The tagged Hemoclip method was developed to address this problem.¹⁰³ It requires a skin incision and dissection down to where the Emergency Physician believes the FB to be based on plain radiographs. Prepare two or three Hemoclips with a long silk suture attached to each one. Place them into the Hemoclip applier. Dissect down to where the FB is believed to be located. Place two or three Hemoclips into the depths of the wound. Obtain repeat radiographs to show the relationship of the FB to the Hemoclips. Remove all but the closest Hemoclip. Dissect toward the Hemoclip and the FB. Identify and remove the FB. Remove the Hemoclip. Repeat the procedure after placing two or three additional Hemoclips if unable to exactly localize the object. Follow the trail of Hemoclips to the FB.

FIGURE 120-8. Paper clip localization of a FB. **A.** The transducer (P) is placed over the FB. (A = proximal end of FB, B = distal end of FB). **B.** US of the FB (arrows). The paper clip (curved arrow) is seen at the proximal end of the FB with a comet tail artifact (arrowheads). **C.** US through the distal end of the FB. The paper clip is again seen (curved arrow). (Used with permission from Creel SA, Girish G, Jamadar DA, et al: Sonographic surface localization of subcutaneous foreign bodies and masses. *J Clin Ultrasound* 2009; 37:158–160.)

NEEDLE GRID LOCALIZATION

The grid principle may be used to remove superficial and nonlinear radiopaque FBs after they have been identified on plain radiographs. Clean, prep, and anesthetize the skin. Insert three 25 gauge, 1.5 inch needles into the skin near the estimated location of the FB and at right angles to each other. Obtain two orthogonal plain radiographs. This process can be repeated, each time moving the needles slightly until one is superimposed on the FB. Determine the cutaneous position of the FB by noting its position within the needle grid. Mark this position on the skin. It must be remembered that this technique does not provide a true three-dimensional image since divergence and parallax distortion of images occur on the radiographs.³

The Emergency Physician must recall that tendons and other structures may block the planned path to the object.¹⁵ Make a 0.5 to 1.0 cm incision in a plane perpendicular to the long axis of the FB to an appropriate depth or dissect along the path of the closest needle.³⁸ Identify and remove the FB. A drawback of this technique is the potential for dislodging of the needles with attendant repeated trips to the Radiology Department. The use of fluoroscopy will prevent this problem.

CROSS-NEEDLE GUIDED TECHNIQUE

A cross-needle guided technique can be used if the FB is superficial. Precise identification of the superficial FB is necessary with this technique. Localization of a small FB requires meticulous insertion of the first needle. Apply topical local anesthetic directly over the FB site or perform a regional nerve block. Injecting local anesthesia in the tissue site before inserting the first needle may lead to

tumescence and loss of the FB. Therefore, using topical anesthesia or a regional nerve block is recommended. Insert a 23 gauge needle tip into the skin 5 to 10 mm away from the FB site, advance the needle below the FB, and put upward and forward pressure on the needle until it emerges out the other side. Inject the surgical site with lidocaine. Insert a second 23 gauge needle in the same manner and below the FB perpendicular to the first needle to help localize the FB and propel it toward the surface of the skin. Use a #15 scalpel to bluntly dissect directly over the fixed FB and remove it.¹⁰⁴

MAGNET REMOVAL

Another technique reported to have a good success rate in removing metallic FBs uses a hand-held magnet.^{105,106} Confirm the presence of a suspected metallic FB using radiographs or US. Prepare, drape, and anesthetize the area. Slightly enlarge the entry wound to permit entrance of the magnet tip. Apply a sterile US transducer cover or glove over the magnet. Gently probe the wound track with the magnet until a “click” is appreciated. Withdraw the magnet with the FB attached to the magnet. Perform further and more directed wound exploration with the magnet if resistance is met. Magnets have been used to localize a metallic FB as the attraction will often create a characteristic “hilliness” in the soft tissue. This localization leads to smaller incisions and reduced scar tissue formation.¹⁰⁷

FLUOROSCOPIC TECHNIQUES

Fluoroscopy offers an excellent aid in the removal of radiopaque FBs.¹⁰⁵ Make an incision over the FB as judged from plain

radiographs. Localize the FB under fluoroscopy. Guide a curved hemostat to the FB with brief intermittent exposures of the fluoroscopy unit.¹⁰⁸ Grasp and remove the FB. This procedure exposes the Emergency Physician's hands to radiation and may risk damaging structures in the wound by blind manipulation of the hemostat.¹⁰⁹

The paper clip and needle localization techniques described previously can be applied under fluoroscopy. Rotating the site of injury under direct fluoroscopy may improve the ability to judge the location of the FB in three dimensions and aid in its removal. Intermittent exposure with a fluoroscope can allow repositioning of the needles until the FB is localized between two needles or at the tip of a single needle. Make a small incision carried down to the FB and remove it.^{109,110}

A modified "paired" needle technique involves placing two pairs of needles under fluoroscopy. The initial needle is placed in between the c-arm and the FB so that the FB falls directly in the "shadow" of the needle. The second needle is then placed in the same line as the first, but distal to the FB. This process is repeated in a second plane perpendicular to the first view. The pairs of needles create two vectors, the intersection point of which will provide an accurate incision leading to precise dissection and removal.¹¹¹

Additional techniques using fluoroscopy and neurosurgical stereotactic devices have been described.³ The cost, availability, and practicality make these approaches unattractive in the Emergency Department and therefore, they are not discussed further.

ULTRASONOGRAPHIC REMOVAL

There are a multitude of different approaches to the US-guided removal of subcutaneous FBs.^{51,54-56,64,112} A detailed working knowledge of the pertinent anatomy is essential. Locate and mark the location of the FB. Clean, prep, and anesthetize the skin. Insert a needle under US guidance. The US monitor screen will display a hyperechoic linear object with posterior reverberation effect. Guide the needle under US until it touches the FB. Make a skin incision down to the FB. The addition of a second needle in a perpendicular plane can enhance the object's localization.⁵⁵ Insert closed hemostats or forceps to approach the FB.^{55,112} Insert the hemostat or forceps along the plane of the FB. Open the jaws of the instrument under US guidance (Figure 120-3). The FB can be removed under US guidance once within the grasp of the hemostat or forceps. **Always rescan the area after the FB is removed to ensure that no additional fragments remain.**

One of the challenges associated with this technique occurs when the FB is pushed away by the forceps. This difficulty may be avoided by using the US transducer or a free finger to apply pressure to "fix" the FB in one spot to facilitate its removal.^{113,114} Certain materials (e.g., glass) may be difficult to grasp with the technique described above.

One adjunct to US-guided FB extraction is hydrodissection. This involves guiding a small needle under real-time US to the FB. Lidocaine is injected to dissect away the surrounding tissues. This allows for more precise visualization and removal of the FB.^{10,109} A more detailed description of US-guided FB removal is available in Chapter 121.

AFTERCARE

It is often prudent to take postextraction radiographs to ensure complete removal of the FB, especially if multiple objects are involved or if there is concern about the object fragmenting.¹¹⁵ Carefully irrigate and debride the wound of all epidermal fragments.³ The most effective form of wound preparation and cleansing is jet lavage irrigation with normal saline to decrease the bacterial load in the wound and the risk of developing infection.¹¹⁶ This can be performed with

a commercially available device or a 35 mL syringe armed with a 19 gauge angiocatheter or blunt needle.¹⁹ Studies of simple pediatric wounds have found that using drinkable tap water to irrigate wounds is a good alternative to saline, as it shows similarly low infection rates.¹¹⁷ The recommended volume for irrigation is 50 to 100 mL/cm of wound, although gross contamination should be taken into account.¹¹⁸ Soaking wounds is not recommended. Soaking may adversely affect wound repair and healing.¹¹⁸ The quality of mechanical cleaning is important to wound prognosis.¹ Cleaned, thoroughly irrigated, and debrided wounds with a good blood supply do not require antibiotics and may be sutured closed after removal of the FB. Arrange follow-up in 5 to 7 days for suture removal.

Consider delayed primary closure or healing by secondary intention if complete cleansing of the wound is not assured or if the wound is at significant risk for infection for other reasons.^{19,119} Delayed primary closure involves packing the wound open for 4 to 5 days. Reassess it and close it primarily if the edema has resolved, no infection is present, and exudate has been removed. This technique results in minimal tissue damage. It is especially useful in clean contaminated and contaminated wounds with a 90% success rate in appropriate patients.

Antibiotic therapy may be considered for those with wounds that are at significant risk for infection. **Antibiotics are not a replacement for proper wound care.** Infection rates for traumatic wounds range from 4.5% to 6.3%. High-risk wounds are bites, burns, wounds associated with cartilage injury, contaminated wounds (e.g., feces, saliva, or soil), crush injuries, wounds associated with frostbite, wounds associated with open fractures, puncture wounds, wounds associated with tendon injuries, and wounds in immunocompromised patients; these wounds should be considered for antibiotic therapy.^{120,121} Close follow-up is especially important in these patients. Prophylaxis for endocarditis is not recommended unless FB removal is undertaken through an area of an established infection.¹²² Splint the involved extremity if the FB is near a joint, a highly mobile region, or a vital structure to prevent injury and/or migration of the FB if the patient is referred for delayed removal.¹⁵ A more complete discussion on wound cleansing, wound irrigation, and the general principles of wound management can be found in Chapter 114.

TETANUS PROPHYLAXIS

Tetanus prophylaxis must be considered for wounds involving FBs. Wounds that are avulsions, burns, contaminated (e.g., feces, saliva, or soil), crushing, frostbite, punctures, or resulting from missiles are considered tetanus prone. Risk factors such as age over 65 years, diabetes, and intravenous drug abuse place patients at higher risk to develop tetanus. Special attention should be placed on these patient groups presenting with minor wounds.¹²³ Studies have found that up to 26% of patients who reported they were up to date with tetanus vaccination were confirmed not to be, while a further 30% were indeterminate.¹²⁴ **It is vital to investigate a patient's tetanus status and vaccinate according to the accepted guidelines.**^{54,125} For patients who have had three or more doses, those who received their previous dose within 5 to 10 years presenting with a nonclean and minor wound should receive the Tdap booster (preferred over the Td booster). Patients who have gone more than 10 years since their last dose should also receive the booster regardless of wound type. All patients in whom there have been fewer than three doses or an uncertain vaccination history should receive the vaccine booster. Of these patients, those with complicated or contaminated wounds should receive the tetanus immunoglobulin (TIG) in addition to the vaccine booster.¹²⁵ Emergency Physicians continue to fail to offer appropriate postexposure prophylaxis even in patients who able to describe their vaccination history accurately.¹²⁶ Refer to Chapter 114 for more complete details regarding tetanus prophylaxis.

COMPLICATIONS

The removal of embedded FBs is relatively free of complications if properly conceived. **Care must be taken to document the functional and neurovascular status prior to and after any significant manipulations.** Appropriate referral of complicated cases (e.g., FBs located deep in the hands, the feet, or near vital structures) will lessen the risk of unfavorable outcomes. Infection remains the most common complication of a retained FB, even when the object itself is not contaminated.¹²⁷ Aseptic technique and avoidance of excessively prolonged manipulation and searching for embedded FBs are important to prevent introducing infection into a previously sterile area. In cases where the FB cannot be found, it may be necessary, although less than ideal, to wait for abscess formation to pinpoint the location of an object.³ Referral for additional imaging and removal may be appropriate. The patient must be advised in detail of the likely course, and follow-up must be assured and documented.

SUMMARY

Virtually all embedded subcutaneous FBs should be identified and located through rigorous assessment of every traumatic wound and by maintaining a high index of suspicion. The history and physical examination should guide the search for retained FBs and the approach to locating them. Most FBs are visible on plain radiographs. Wounds in which a radiopaque FB may be retained should be imaged with standard radiographs. Bedside US should be used to assist in the identification and removal of subcutaneous FBs. Additional diagnostic imaging with CT or MRI may be indicated if a FB is still suspected but not identified by radiographs or bedside US. Several techniques are available to aid in localization and removal of the FB. A decision must be made regarding the necessity of immediate or urgent removal in the Emergency Department or by referral to a specialist. Inert FBs that are unlikely to cause long-term complications may be left in situ. Provide verbal and written information to the patient who explains the reasoning behind this conservative approach if a FB is left in the tissue. Appropriate wound care is crucial to satisfactory healing. Postprocedure follow-up must be addressed.

Ultrasound-Guided Foreign Body Identification and Removal

Daniel S. Morrison and Chirag N. Shah

INTRODUCTION

Retained foreign bodies are associated with up to 1.9% of wounds.¹ The presence of a foreign body in a wound increases the incidence of a wound infection.² Retained foreign bodies are a major cause of litigation against Emergency Physicians.^{3,4} A high index of suspicion for a retained foreign body must be maintained whenever there is the potential for a foreign body in a wound.⁵⁻⁷

This chapter focuses on the identification and removal of subcutaneous foreign bodies using bedside Emergency Department ultrasound (US).

Foreign bodies may be small, leave no skin entry marks, and consist of many different types of material. Almost any object (i.e., solid, liquid, or gas) can become a foreign body and present itself in a location where it should not reside. Standard plain radiographs and fluoroscopy are good at identifying radiopaque objects (e.g., metal, gravel, and glass).⁸⁻¹⁴ Glass accounts for up to 50% of missed foreign bodies using the physical examination and radiographs.¹⁵ The ability of techniques to identify a foreign body vary by the size and composition of the foreign body.¹⁰ Magnetic resonance imaging (MRI) and computed tomography (CT) are useful to detect foreign bodies.^{13,16,17} These are expensive imaging modalities and the images vary depending on the length of time the foreign body has been present.¹⁷ Certain foreign bodies may produce artifacts that diminish the MRI and CT image qualities.¹³ Plastic, hair, vegetative material, and rubber are not radiopaque and are not routinely identified on plain radiographs.^{6,8,9,11-14,18-20} US identifies radiopaque foreign bodies. **US can detect foreign bodies that are not radiopaque due to their different echotexture in relation to surrounding structures.**^{6,9,16-33} The sensitivity and specificity of US in detecting retained soft tissue foreign bodies have been reported as 72% and 92%, respectively.¹⁵ Subgroup analysis of radiolucent or wooden foreign bodies demonstrated a sensitivity of 96.7% and specificity of 84.2%.¹⁵ US can detect foreign bodies that are very small.³⁴

ANATOMY AND PATHOPHYSIOLOGY

Foreign bodies can be present in almost any part of the body. Foreign bodies can be detected with US in nontraditional places. They have been identified in the eye, esophagus, and tongue using US.^{32,35,36} Foreign bodies isolated to small spaces (e.g., the web spaces of the hand) may not be identified due to the size of the US transducer footprint and an anatomic location that is difficult to scan.²⁹

Not diagnosing foreign bodies can be dangerous for the patient and lead to an increased risk of complications. Legislation to introduce an aluminum penny into circulation in the United States in 1973 was defeated in part by Pediatricians' and Pediatric Radiologists' concern that these new coins would not be easily identified on plain radiographs.³⁷ Patients with retained lead foreign bodies can have statistically significant elevated blood lead levels as compared with matched controls.³⁸

Foreign bodies have specific US characteristics. Smooth and flat surfaces typically produce a dirty shadowing or reverberation artifact.^{39,40} Irregular surfaces with a small radius or curvature produce a cleaner shadow (Figure 121-1). Glass and metal typically produce a ring-down or reverberation artifact (Figure 121-2).^{12,26,31,32,39,41} A wood foreign body produces a bright echogenic reflection with a strong acoustic shadow (Figure 121-3).^{6,12,32,42} Foreign bodies residing in soft tissue longer than 24 hours can cause an inflammatory reaction that creates a hypoechoic rim around the echogenic foreign body (Figure 121-4).³⁹ Secondary signs (e.g., edema and inflammation) may not be seen in cases of retained foreign bodies.⁴³

INDICATIONS

Patients with a foreign body sensation or soft tissue mass should be considered to have a foreign body until ruled out.^{5,18} Foreign bodies can migrate great distances from the original insertion site. This requires the Emergency Physician to maintain a high index of suspicion for a foreign body.⁴⁴ The ideal treatment window for

FIGURE 121-1. US image of a subcutaneous pebble. Notice the hyperechoic short radius and tight curvature. The pebble casts a strong acoustic shadow as it blocks transmission of the US beam.

retained foreign body removal is within 24 hours.¹⁵ This time frame allows for visualization of the entry and exit wounds, decreased inflammation, decreased induration, and decreased scarring.¹⁵ Any patient in whom the Emergency Physician has any index of suspicion for a foreign body should have additional investigations. Wood, thorns, spines, vegetative foreign bodies, dirt, clothing, and heavily contaminated foreign bodies should be removed immediately. Remove foreign bodies immediately with the potential for migration or entrance into the systemic circulation. It is generally believed that glass, metal, and plastic are inert and can be removed electively as they tend to be encysted by scar tissue.

Foreign body removal is dependent on the specific situation, physician preference, and patient characteristics. Remove the foreign body in patients who have persistent pain, neurapraxia, impairment of function, limitation of range of motion of a joint, or psychological distress. Remove foreign bodies adjacent to bone within 96 hours because they can cause osteomyelitis.⁴⁵ **Any patient from whom a foreign body, especially wood, was removed should be considered for further investigation to ensure there are no additional foreign bodies or a fragment of the removed foreign body present.**²⁰

CONTRAINDICATIONS

US is a safe imaging modality without any known ionizing radiation. There are no known contraindications to using US to identify and assist in the removal of a foreign body.

EQUIPMENT

- US machine
- High-frequency linear US transducer, 7.5 MHz or greater
- Sterile US transducer cover or glove
- Skin cleansing solution (e.g., chlorhexidine or povidone iodine)
- Sterile US gel or other type of sterile gel (e.g., Surgilube)
- #11 scalpel blade
- Suture kit or individual components (i.e., sterile drape, gauze pads, hemostat, and forceps)
- Local anesthetic solution, usually lidocaine
- 5 mL syringes
- 27 gauge needles
- 18 gauge needle to draw up the local anesthetic solution
- Skin marking pen
- Paper clips
- Stand-off pad or a small (e.g., 50 or 100 mL) saline bag

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Cleanse the skin of any dirt and debris. Apply a liberal quantity of US gel over the area in which the foreign body is suspected. Use a high-frequency linear US transducer to search for the foreign body. Look for signs of the foreign body such as reverberation artifact, comet-tail artifact, acoustic shadowing, a hypoechoic rim surrounding an echogenic structure, or any other signs associated with foreign bodies. **It is recommended that a combination of axial, sagittal, coronal, and oblique scans are obtained due to the various ways a foreign body may be oriented.**⁴⁶

Foreign bodies may be very superficial. It may be necessary to change the focal zone on the US machine. An acoustic interface may assist in locating a superficial foreign body. Apply a stand-off pad over the site of the foreign body. This can be either a commercially available stand-off pad, a small saline bag in which the air is removed, or a glove filled with saline or US gel.^{19,47} The water bath technique works well for the hands and feet.⁴⁸ Place the body part in a water-filled container. Place the US transducer in the water-filled container without contacting the patient's skin. Identify the presence of a foreign body. Identify and localize the foreign body to make the removal easier for the patient and the Emergency Physician.

TECHNIQUES

PAPER CLIP LOCALIZATION AND REMOVAL

Mark the location of the foreign body on the patient's skin. It is helpful to use a metal foreign body (i.e., the paper clip) to create a shadow to locate the foreign body. The metal paper clip will cast a distinct shadow.⁴⁹

Identify the foreign body on US. Place the US transducer on the patient's skin above the foreign body. Turn the US transducer so its long axis is aligned with the long axis of the foreign body. Insert the tip of an unfolded paper clip between the US transducer and the skin surface. Slowly advance the paper clip until the shadow it casts aligns with the leading edge (i.e., the most superficial aspect) of the foreign body (**Figure 121-5**). Use a skin marker to mark this location on the patient's skin. Rotate the US transducer 90° to visualize the short axis or cross-sectional view of the foreign body. Insert the tip of the unfolded paper clip between the US transducer and the patient's skin. Mark the location on the patient's skin where the shadow cast by the paper clip aligns with the leading edge of the foreign body. **The intersection of these two lines is where the leading edge of the foreign body resides under the skin.**

Prepare to remove the foreign body. Prepare a 5 mL syringe with a 27 gauge needle and local anesthetic solution. Cleanse the patient's skin with chlorhexidine or povidone iodine solution and allow it to dry. Apply sterile drapes to form a sterile field. Inject local anesthetic solution subcutaneously around the skin markings over the leading edge of the foreign body.

FIGURE 121-5. Paper clip localization of a foreign body. The wood foreign body has a bright echogenic reflection and casts an acoustic shadow. The paper clip casts a ring-down or reverberation artifact that is lined up over the leading edge or most superficial most aspect of the foreign body. **A.** Long axis US view. **B.** Short axis US view.

FIGURE 121-6. Retrieval of the foreign body. US image of the forceps approaching a wood foreign body. Note that the arms of the forceps are open and in line with the foreign body.

Prepare the US transducer. Apply US gel to the footprint of the US transducer. Apply a sterile transducer cover or a sterile glove over the US transducer. Squeeze any air out of the space between the US transducer and the cover. Apply sterile US gel on the transducer cover.

The Emergency Physician should don sterile gloves. The use of a hat, face mask, and sterile gown is not necessary for this procedure. Grasp the US transducer with the nondominant hand. Align the long axis of the US transducer along the long axis of the foreign body and approximately 3 to 4 mm proximal to the skin markings. Aim the syringe containing the local anesthetic solution downward and in the direction of the foreign body. Slowly insert and advance the needle through the skin mark under US guidance while slowly injecting a small volume of local anesthetic solution. The injection of local anesthetic solution around the foreign body creates a hypoechoic halo that helps with the identification of the foreign body.⁵⁰ Stop advancing the needle when the tip reaches the foreign body. Remove the needle without moving the US transducer.

Use a #11 scalpel blade to make a small skin incision just proximal to the skin mark and in the previously anesthetized area. Insert the jaws of a closed hemostat or the arms of a closed alligator forceps into the skin incision. Advance the instrument under US guidance and bluntly dissect down to the foreign body. Align the tip of the instrument with the leading edge of the foreign body (**Figure 121-6**). Open the instrument, grasp the foreign body, and remove it.

NEEDLE LOCALIZATION AND REMOVAL

Identify the foreign body using US. Cleanse the skin, apply sterile drapes, prepare the syringe, and prepare the US transducer as described above. Infiltrate local anesthetic solution subcutaneously in the area overlying the foreign body. Align the long axis of the US transducer with the long axis of the foreign body. Insert a 27 gauge needle in front of the US transducer. Slowly advance the needle under US guidance until its tip is against the foreign body. Injecting local anesthetic adjacent foreign body will often detach the foreign body from the adjacent tissue and facilitate removal.⁵¹ Release the needle with the dominant hand and grasp a #11 scalpel. Insert the #11 scalpel blade along the needle until the tip of the blade is at the tip of the needle. Remove the scalpel blade and needle without moving the US transducer. Insert a forceps, hemostat, or alligator forceps

along the incision track under US guidance. Open the instrument, grasp the foreign body, and remove it.

ASSESSMENT

It is important to rescan the area after removal of the foreign body to ensure there is no additional foreign body or a retained piece of the original foreign body that needs to be retrieved. Foreign bodies may not be removed in their entirety. A second foreign body may be present in an injury and not visible on the initial US scans.

AFTERCARE

Ensure that the foreign body is completely removed. There are many different thoughts on the care of wounds. Copiously irrigate the area. There is no evidence that using tap water to cleanse acute wounds in adults increases infection, and some evidence suggests that it reduces infection rates.⁵² There is no strong evidence that cleansing wounds increases healing or reduces infection.⁵² Close any lacerations from the wound itself or from the procedure to remove the foreign body. There is no strong evidence to support the use of antibiotics in simple nonbite wounds.⁵³ Wounds associated with foreign bodies are at an increased risk for infection. **Instruct the patient of the signs and symptoms of an infection.** In one review, 44.4% of all subjects with a foreign body removed were prescribed antibiotics.⁵⁴ When consultants were used in the care of these patients, the number rose to 84.4%.⁵⁴ A short course of antibiotics may be appropriate to prevent iatrogenic septic complications or sequelae caused by mobilization of the foreign body.⁵¹

COMPLICATIONS

Foreign bodies and the procedures to remove them have been associated with infections (e.g., flexor synovitis, cellulitis, gas gangrene, abscesses, osteomyelitis, fungal infections, and lymphangitis), laceration of adjacent structures (e.g., nerves and tendons), neurapraxia, inclusion cysts, fractures, arthritis, and even an angiosarcoma.^{14,26,45,55,56} Attempts are made to identify and remove all foreign bodies, but some of them may be missed. A retained foreign body can later lead to similar signs and symptoms.^{57,58} **It is important to investigate and remove foreign bodies in a timely manner.**

CLINICAL EXAMPLES

Cases will be used to illustrate many of the complexities of removing a foreign body.

An elderly male presented with the complaint of a piece of wood lodged in his hand while working with a piece of bark. The patient had no imaging but did have local exploration that revealed a foreign body, which was removed. The patient left the Emergency Department prior to receiving discharge instructions or a prescription for antibiotics. The patient presented the next day with increased pain. He had a hand series of plain films which were interpreted as negative (**Figure 121-7**). The patient presented to the Emergency Department 69 days after the original injury. By this time, the patient had multiple courses of antibiotics, saw a Hand Surgeon the day before who indicated he could not help him, and was referred to the Emergency Department. The patient's physical examination revealed induration and tenderness on the palmar aspect of the wrist (**Figure 121-8**). The bedside US revealed a subcutaneous collection of fluid (**Figure 121-9A**) and a foreign body (**Figures 121-9B and 121-9C**). A Hand Surgeon was consulted due

FIGURE 121-7. Plain radiographs of the hand. **A.** Anteroposterior view. **B.** Oblique view. **C.** Lateral view.

to the duration the foreign body was in place and the associated US findings (i.e., an abscess). The foreign body was removed and the abscess drained in the Operating Room.

Another patient fell on a glass table and broke the top with her upper extremity. She presented to the Emergency Department by paramedics soon after the injury. The patient had numerous small lacerations on her upper extremity. Plain radiographs were negative for any foreign bodies. Bedside US was performed by the Emergency Physician. A glass foreign body was seen (**Figure 121-10**). The glass was removed in the Emergency Department without difficulty.

SUMMARY

Foreign bodies are a major source of litigation. They are often not detected on physical examination or standard plain radiographs and can be associated with complications. A high index of suspicion must be maintained when the patient has a laceration, soft tissue mass, or foreign body sensation. US can be used to identify and remove foreign bodies in the Emergency Department.

Hair Tourniquet Management

Asim A. Abbasi

INTRODUCTION

Hair tourniquet syndrome or hair-thread tourniquet syndrome refers to the circumferential constriction of a finger, a toe, or the genitalia by hair or cloth fibers (**Figure 122-1**). Constriction of the tourniquet can lead to pain, tissue injury, and tissue necrosis if untreated. Infants and young children under 2 years of age are predominantly affected.¹⁻³ Genital hair tourniquets that affect the clitoris or labia are not as common and tend to occur in older children.³⁻⁵ Hair tourniquets can rarely affect oral structures.⁶⁻⁸

There can be various clinical presentations. Fussiness and parental perception of pain are the common presenting signs.

FIGURE 122-1. A toe tourniquet and the distal edema. (Used from www.upload.wikimedia.org/wikipedia/commons/d/d3/Hairtourniquet.JPG.)

Always consider a hair tourniquet in the differential for an inconsolable infant. The tourniquet may often be missed during a routine examination as the constriction may be mistaken for a physiologic anatomic crease on the infant's digit. Risk factors include increased maternal shedding of hair postpartum (e.g., one cause of telogen effluvium), co-bathing of the mother and infant, and co-laundering of clothes of others with those of the infant.^{9,10}

Prompt diagnosis allows for treatment and prevention of further pain and morbidity. Mechanical release has been the mainstay of tourniquet release. Recent studies have proposed chemical depilatory agents as the primary modality to release a hair tourniquet.⁴

ANATOMY AND PHYSIOLOGY

The hair fiber is an elastic structure that can stretch when dry to 20% to 30% of its original length.¹¹ It can stretch up to 50% of its original length when the hair fiber becomes wet.¹¹ **A single strand of hair can be almost transparent, especially when wet.**¹² The presumed process of the hair tourniquet syndrome begins when moist or wet hair becomes entrapped within the confines of the infant's mitten or socks. Repetitive movement of the infant's flexed digit and contraction of the hair as it dries lead to constriction of the affected digit. The hair may cut into and become embedded within the epidermis. There may be reepithelialization of skin over the embedded hair.

Restriction of lymphatic drainage leads to local tissue edema distal to the constriction. Compromise of the vascular supply can lead to ischemia and necrosis. Erosion of the underlying bone with tendon involvement has been demonstrated in several cases.^{9,13} The urethra can be involved with a penile tourniquet.¹⁴

A knowledge of the neurovascular supply of the affected appendage will avoid injury in the mechanical release of a hair tourniquet with an incision. Each finger and toe has four neurovascular bundles with each consisting of a digital artery and nerve. One bundle is located on each of the medial and lateral sides of the ventral and dorsal aspects of the digit. The neurovascular bundles of the penis and clitoris are located on their respective dorsal surfaces at the 11 o'clock to 1 o'clock positions. The location of the incision will depend on whether the hair tourniquet is on the finger, toe, or genitalia.

INDICATIONS

All hair tourniquets should be removed urgently to prevent further underlying tissue injury. Removal of hair tourniquets from the fingers and toes can be performed in the Emergency Department. Any concern for an underlying tendon injury or lack of improvement of tissue edema after removal of the hair tourniquet warrants an urgent referral to an Orthopedic Surgeon. Hair tourniquets involving the genitalia can often be removed with simple manipulation or a superficial incision. Those that are difficult to remove require an emergent consultation with a Gynecologist or Urologist.

CONTRAINDICATIONS

There are no proposed or studied absolute contraindications to the removal of hair tourniquets. The removal will immediately prevent or decrease the risk of tissue necrosis and morbidity. The use of chemical depilatory agents is not recommended on or near mucous membranes due to concerns for chemical irritation.

EQUIPMENT

- Sucrose solution for soothing the infant
- Gloves
- Topical analgesia (e.g., EMLA or LMX)
- Local analgesia without epinephrine
- Povidone iodine solution or chlorhexidine
- Needles, 25 or 27 gauge
- Syringes, 3 and 5 mL
- #11 scalpel blade
- Blunt probe
- Fine-tipped forceps
- Fine-tipped scissors
- Commercial depilatory cream (optional)

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the removal procedure and the anesthesia to the patient and/or their representative. Obtain an informed consent for the anesthesia and the removal of the hair tourniquet. Place the patient on a gurney. Secure infants and young children with a papoose and the affected extremity exposed (Chapter 232).

Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine and allow it to dry. Provide anesthesia if needed. Perform a digital block or a block of the penis or clitoris (Chapter 156). Draw up local anesthetic solution into a syringe armed with a 25 or 27 gauge needle. Perform the regional block (Chapter 156). Perform a procedural sedation if necessary to control the patient (Chapter 159). This will prevent movement of the patient and accidental injury to underlying structures.

TECHNIQUES

MECHANICAL REMOVAL ON THE DIGITS

Grasp hair tourniquets that are easily visible, superficial, and not deeply embedded with a fine-tipped forceps. Unwind the hair tourniquet. Tourniquets that are tight or flush against the skin make grasping difficult. Insert a blunt probe underneath the hair tourniquet if possible (**Figure 122-2A**). Make an incision with the scalpel blade using the metal probe as a cutting board (**Figure 122-2B**). Cutting on the probe prevents accidentally cutting into the underlying skin.

Sometimes the hair tourniquet cannot be released using the techniques described above. This may be due to the hair tourniquet being deeply embedded within the skin, the skin reepithelializing over the hair thread, or worsening edema of the finger preventing visualization. Anesthetize the digit or provide procedural sedation. Make a direct incision into the digit longitudinally (**Figure 122-3A**). **Incise from the proximal to the distal end and at the 3 o'clock or 9 o'clock position.** Incising at these positions decreases the risk of

FIGURE 122-2. The use of a probe to remove a hair tourniquet. **A.** Probe insertion. **B.** Cutting the tourniquet.

A

B

FIGURE 122-3. The incision remove a hair tourniquet. **A.** The lateral incision. **B.** The dorsal incision.

damage to the digital nerves and arteries. Some make the incision at the 12 o'clock position as an alternative (**Figure 122-3B**). The incision should be made to the depth of the bone to ensure that the constricted hair thread is released completely.¹⁵ The incision will be clean, have well-approximated edges, and be allowed to heal by secondary intention.

DEPILATORY REMOVAL ON THE DIGITS

There are several studies that have employed a chemical depilatory agent (e.g., Nair or Veet).^{4,16} This approach was initially proposed as an adjunct to mechanical removal and has transitioned to a primary modality. The thioglycolate-based depilatory agents break the disulfide bonds in keratin and allow the hair strand to weaken. The advantage of this technique is that it is nearly painless except stinging and needs no incisions. **The chemical depilatory agents will have no effect on cloth or synthetic fibers (e.g., cotton, polyester, and rayon).**^{17,18} They are not recommended for areas in proximity to mucous membranes.

Apply the depilatory agent to the area around the hair tourniquet. Allow it to work for 20 to 30 minutes. Wash off the depilatory under running warm water in the sink. Attempt to manually remove the remnants of the hair tourniquet. The depilatory agent can be applied for a second time if necessary.

GENITAL TOURNIQUET REMOVAL

Remove hair tourniquets on the penis or clitoris. Grasp hair tourniquets that are easily visible, superficial, and not deeply embedded with a fine-tipped forceps. Unwind the hair tourniquet. Tourniquets that are tight or flush against the skin make grasping difficult. Insert a blunt probe underneath the hair tourniquet if possible. Make an incision with the scalpel blade using the metal probe as a cutting board. Cutting on the probe prevents accidentally cutting into the underlying skin.

Hair tourniquets embedded within the epidermis or with epithelialization over it are harder to remove. **Concern for ischemia requires emergent Gynecology or Urology consultation. Prepare for a direct incision if the consultant is not immediately available.** Apply topical anesthesia to the area. A delay in the topical anesthetic taking effect may require the performance of regional anesthesia or procedural sedation. Make a superficial incision on

the inferior surface on the penis or clitoris at the 4 o'clock or 8 o'clock position (**Figure 122-4**). Incising at these positions decreases the chance of damaging any neurovascular structures. **Stay superficial to the fascia when making the incision.** Make successive strokes with the scalpel blade deeper through the tissue until the constriction is released. **Do not cut into the corpora to prevent massive bleeding that is difficult to control.**

An alternative to incising is to initiate chemical depilatory treatment to the penis as described above.⁴ The burning of these depilatory agents may require topical anesthesia, regional anesthesia, or procedural sedation. **Chemical depilatory agents are not recommended for clitoral hair tourniquets due to the proximity of mucous membranes.** Consult a Gynecologist urgently if simple isolation and incision of a clitoral hair tourniquet is not possible.

ASSESSMENT

Assess the patient's skin after the release of a hair tourniquet. Note and document any lacerations or abrasions from the hair tourniquet or the removal process. Check the neurovascular status of the affected digit after the procedure to ensure there is no compromise.

FIGURE 122-4. The penile incisions (arrows) to remove a hair tourniquet.

AFTERCARE

Reassess the patient after the release of a hair tourniquet and they have had time to sit calmly. There should be a noticeable improvement in the swelling. There may not be complete resolution of the edema. Recheck and document the neurovascular status of the affected digit after the procedure to ensure there is no compromise.

Verify the patient's tetanus status if an incision is made into the skin. Topical antibiotic ointment over the incision site can be used to prevent an infection. Prescribe antibiotics for 3 to 5 days if there is concern for contamination of the wound, contamination during the release of the hair tourniquet, or a laceration to the skin. Arrange follow-up with the primary physician to ensure that the affected tissue has returned to its normal caliber and there is no evidence of infection.

Provide anticipatory guidance to the caregivers to prevent a recurrence. Examine the baby's toes, fingers, and genitalia after every bath. Launder mittens and socks inside-out to prevent accumulation of hair fibers.¹⁹ Launder the infant's clothes separately. Remove and inspect the infant's socks and mittens with diaper changes.

COMPLICATIONS

Compromise of the neurovascular status of the appendage may occur from the hair tourniquet or iatrogenic injury during the removal. Tenosynovitis of the digit may result if the tendon sheath was affected. Infection and cellulitis may also occur. Transient chemical irritation from the depilatory agent has been reported with its increasing use.

SUMMARY

The hair tourniquet syndrome is a rare diagnosis in infants. It can involve a finger, a toe, or the genitalia. The "hair" can be a hair or cloth fibers. Untreated hair tourniquets can lead to edema, strangulation, and ischemia. Release of the hair tourniquet can often be performed with a simple unwinding of the hair, a direct incision into the underlying tissue, or the application of a topical chemical depilatory agent. Close follow-up is required to ensure complete resolution of the edema and a normal neurovascular status.

Tick Removal

Laurie Krass and Dhara Amin

INTRODUCTION

Ticks are blood-feeding external parasites that pose a significant infectious disease risk to humans and animals worldwide (**Figure 123-1**). They have been implicated as vectors in the transmission of more than 200 pathogens (e.g., babesiosis, ehrlichiosis, Lyme disease, Rocky Mountain spotted fever, tick-borne relapsing fever, tick paralysis, and tularemia).¹⁻³ Disease transmission occurs when stomach contents and saliva from the tick are introduced into the host during the blood-feeding process. Transmission of infectious agents by ticks is closely related to the duration of tick attachment and blood-feeding. Lyme disease is the most common tick-borne illness in the United States.⁴ The risk of contracting it increases significantly once a tick has remained attached for more than 24 to 36 hours.^{5,6} This is the time required for bacteria to migrate from the midgut of a tick to the salivary glands.⁵⁻⁷ **The prevention of disease transmission relies on early and effective removal of attached ticks.**⁸⁻¹¹

ANATOMY AND PATHOPHYSIOLOGY

Ticks are arachnids and divided into Argasidae (i.e., soft ticks) and Ixodidae (i.e., hard ticks).¹² Hard body ticks are responsible for the transmission of most human diseases and will be the focus of this chapter. Hard ticks pass through four life cycle stages from birth (i.e., egg, larva, nymph, and adult). They require a blood meal to progress to the next stage of their development.

FIGURE 123-1. Examples of a tick. (Used from www.commonswikimedia.org.)

B

FIGURE 123-2. The specialized mouthparts of the tick. **A.** Photograph. **B.** Artist illustration of the attachment of a tick.

Ticks are often encountered in the late spring, summer, and early fall. Ticks are more prevalent in rural and wooded areas. They like to feed on dark (i.e., covered) and moist areas of the body (e.g., axilla, groin, and scalp). The bite of a tick is painless, often goes unnoticed, and the tick is found attached to the skin.

Ixodes ticks have a shield-like scutum on the dorsum of their body with mouthparts that protrude forward. Nymphs and adults have eight legs. They vary in size depending on life cycle stage. Nymphal ticks are approximately 1.5 mm long. Adult unfed ticks are about 3 mm long, although once fed they can enlarge to 11 mm in length.¹³ Tick coloration varies based on species and stage of feeding. Unfed ticks often appear black or brown. Engorged ticks during or after feeding can appear pink or dark red.¹⁴ Ticks have specialized mouthparts that make their removal difficult (**Figure 123-2**).¹² They screw their mouthparts into the skin in a clockwise direction. Mouthparts include the palps, the chelicerae, and the hypostome. Ticks cut through skin using the chelicerae. Ticks then insert their hypostome, a tube-like structure through which the feeding takes place.¹³ The hypostome has many backward-facing sharp barbs called denticles that prevent the tick from being dislodged. The tick can secrete a cement-like material around the hypostome to secure its attachment to the host while it feeds.¹³ **The longer the tick is attached, the more difficult it becomes to remove it intact. The tick releases its mouthparts from the host after the meal is complete.** It can take anywhere from hours to up to 1 week for an adult tick to finish its blood meal and detach from the host.¹⁵ The difficulty of removing a tick with all parts intact increases the longer the tick remains attached.

INDICATIONS

Remove any tick attached to the skin. Transmission of bacteria, spirochetes, viruses, or other infectious agents is directly related to length of time of attachment. Ticks attached less than 24 hours have a lower risk for transmission of disease.¹⁶

CONTRAINDICATIONS

There are no absolute or relative contraindications to the removal of a tick.

EQUIPMENT

REQUIRED EQUIPMENT

- Povidone iodine solution, chlorhexidine solution, or isopropyl alcohol swabs
- Gloves
- Fine forceps or mosquito hemostat

OPTIONAL EQUIPMENT

- Magnifying headlamp
- 18 gauge needle
- Local anesthetic solution
- 3 mL syringe with a 27 gauge needle
- Skin biopsy punches
- #15 surgical scalpel blade on a handle
- 5-0 or 6-0 nonabsorbable suture
- Specimen container with isopropyl alcohol

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Risks include failure to remove all tick parts and infection. Obtain an informed consent for the procedure. Clean any dirt and debris from the skin. Apply povidone iodine or chlorhexidine solution to the skin surrounding the tick and allow it to dry. An alcohol swab can be used as a substitute.

FIGURE 123-3. Removal of the tick. **A.** The tick is grasped as close to the skin as possible. **B.** Firm upward pressure is applied to remove the tick.

TECHNIQUE

Direct mechanical removal of the tick is the only recommended technique.¹⁵ Grasp the tick with a fine forceps or mosquito hemostat at the tick's head or mouthparts, as close to the patient's skin as possible (**Figure 123-3A**). **Do not crush, puncture, squeeze, or tear the tick's abdomen.** Apply firm and upward pressure to remove the tick (**Figure 123-3B**). **Carefully examine the skin for any remaining portions of the tick's mouthparts.** Gently grasp and remove any retained parts of the tick with fine forceps or the tip of a sterile needle.

Direct upward traction is the preferred method of removal.¹⁵

Some have suggested that a rotary counterclockwise movement combined with a firm pull may be more effective.¹⁷ Another technique that has been described suggests first rotating the tick two complete revolutions around its axis to loosen its attachment prior to pulling it away from the skin.¹⁸ The premise is that the twisting action will disengage the tick's mouthparts. There is not enough information to recommend or refute these methods. **It is not advised to rotate the tick during removal as this may break the mouthparts.**^{19,20}

ALTERNATIVE TECHNIQUES

Some Emergency Physicians prefer a surgical technique to remove the tick and its attachment to the skin. This ensures that no mouthparts are accidentally left in the skin and avoids all contact with the tick. It theoretically eliminates the risk of increasing salivation, regurgitation of midgut contents into the bite, and the increase in disease transmission. Surgical removal may be the preferred method when attempting to remove smaller ticks or nymphs, or when removing a crushed tick from a previous failed attempt at conventional removal.²¹

Clean and prep the skin with povidone iodine solution or chlorhexidine solution and allow it to dry. Inject 0.25 to 0.50 mL of local anesthetic solution subcutaneously immediately underneath the tick's mouthparts. Apply povidone iodine or chlorhexidine solution to the skin again and allow it to dry. Stretch the skin on each side of the tick with the nondominant hand. Apply the skin biopsy punch perpendicular to the skin. **Make sure that the tick is centered within the skin biopsy punch.** Advance the skin biopsy punch downward with a twisting from clockwise to counterclockwise until a loss of resistance is felt. The loss of resistance indicates that the skin biopsy punch is through the epidermis and at the level of the dermis. Remove the skin biopsy punch. Grasp and lift the punched skin plug with forceps. Cut the plug at the dermal-epidermal junction with an iris scissors or a #15 scalpel blade. Alternatively, remove the tick with a limited skin excision using a #15 surgical scalpel blade by making an incision around the attachment site 2 to 3 mm in diameter and depth.²¹ The skin can be closed with a single nonabsorbable suture, closed with Steri-strips, or left open to granulate and heal.

There are several chemically based techniques that have been used to stimulate passive self-detachment of a tick secondary to a lack of oxygen that patients may attempt at home to avoid an Emergency Department visit. These involve coating the tick with noxious materials (e.g., kerosene, fingernail polish, liquid nitrogen, petroleum jelly, rubbing alcohol, vegetable oil, or vinegar) to cause the tick to voluntarily withdraw its attachment.²²⁻²⁴ These techniques have not been shown to be successful.^{15,19,25-27} Techniques that attempt to suffocate the tick are not felt to be useful due to the low respiratory rate of 3 to 10 breaths per hour in a feeding tick.^{15,18,19,23,26,27} The use of a heated object (e.g., a match tip or piece of metal) applied to the abdominal surface of the tick will not induce detachment, can cause the tick to burst and release infectious fluids, and can burn the patient's skin.^{13,28} **Avoid all techniques that prolong the duration of attachment of a tick.** Subcutaneous injection of local anesthesia is ineffective at stimulating the tick from detachment.

Many devices have often been used to remove ticks. There are specific devices that are commercially available and advertised to aid in manual tick removal (**Figure 123-4**). This includes radiofrequency electrodes set to low power.²⁹ Some of these techniques and devices have been tested and are not felt to offer any advantage over forceps removal.^{22,23,27,30}

ASSESSMENT

Carefully inspect the bite site to ensure no foreign material has been retained. Discard the removed tick as testing of the tick is usually not indicated. Place the tick in a specimen container with isopropyl alcohol until testing can be performed by a laboratory or the local public health department if it is desired.

AFTERCARE

Cleanse the area with a mild disinfectant or soap and water. Administer tetanus prophylaxis if the immunization history is not up to date. Instruct the patient that the appearance of any rash or the occurrence of any febrile illness 2 to 12 days after a documented tick exposure requires further medical follow-up. Provide the patient with information regarding the signs and symptoms of Lyme disease and other tick-borne diseases based on geographical area. Instruct the patient to inspect the site twice a day for signs of an infection and return to the Emergency Department or their Primary Care Physician if they develop discharge, drainage, erythema, a rash, swelling, or tenderness at the bite site.

A detailed discussion identifying the types of ticks or the indications for prophylactic antibiotic therapy are beyond the scope of this chapter. Consult the current medical literature or an Infectious Disease Specialist regarding these questions. The decision to prescribe antibiotics for a patient after tick removal should be made on an individual basis based on exam findings concerning for infection. The use of prophylactic oral antibiotics to cover typical skin flora or Lyme disease is not routinely recommended.

Educate the patient about ticks and preventative measures to avoid tick bites. **Prevention is the best protection.** Advise the patient to wear clothes to cover their arms, legs, and torso when outside. Tuck the cuffs of their pants into boots or socks. Apply a repellent (i.e., chemical or botanical) or an insecticide to clothes and exposed skin of people and pets. Avoid high grass and piles of leaves. Avoid contact with animals. Treat any pet dogs and cats with tick collars or liquid treatments monthly as per Veterinarian recommendations. Avoid placing any clothes on the ground outside. Wear light-colored clothing whenever possible. Physically check for the presence of ticks at the end of the activity or the end of the day.

COMPLICATIONS

The major complication of the direct removal technique is the separation of the tick body from the embedded head. Leaving foreign material in the wound can serve as a site for a subsequent infection.^{8,18} Any remaining pieces of the tick should be removed using the tip of a sterile needle, a skin biopsy punch, or sharp dissection with a #15 scalpel blade.

Inadvertent crushing of the tick may allow stomach contents or saliva from the tick to enter the wound. It is theorized that grasping the tick too distal to the head or across the thorax/abdomen could induce regurgitation of midgut contents into the wound and increase the risk of disease transmission.^{8,13,18}

Local complications of tick removal include bleeding and infection. The application of direct pressure will control any bleeding.

A cellulitis presents a few days after the bite and is often due to the ticks feeding process, skin contamination entering the bite site, or retained mouthparts. Carefully inspect the bite site to ensure there are no retained mouthparts. Use a skin biopsy punch to remove the bite site if unsure. Treat the cellulitis with oral antibiotics that cover typical skin flora.

SUMMARY

Ticks are a vector for several diseases with potentially severe complications. They should be removed from the skin as soon as possible. Disease transmission is directly related to the amount of time a tick is attached. The prompt removal is essential to prevention. The only recommended technique for tick removal that has been studied and proven effective is manual detachment using forceps.

Surgical excision is an option for smaller or crushed ticks. Efforts should be made to remove all parts of a tick from the bite site. Any mouthparts left in the skin increase the risk of subsequent infection.

Fishhook Removal

Eric F. Reichman

INTRODUCTION

The presentation of a fishhook embedded in the subcutaneous tissue can be common depending on practice location and season of the year. The patient, or a well-meaning bystander, will often have already attempted removal that was prevented by the hook's barb. The ensuing tissue trauma and patient anxiety can complicate the task for the Emergency Physician. Removal can be difficult because a fishhook is designed not to pull out of a fish's mouth. Several methods of removal have been described.¹⁻¹⁹ The method chosen depends on the type and size of the hook, the depth of penetration, and the anatomic location of injury.

ANATOMY AND PATHOPHYSIOLOGY

Most fishhooks become embedded in the skin and subcutaneous soft tissue. The anatomy of a fishhook is simple (**Figure 124-1**). The long, straight section is known as the shaft. The proximal end of the shaft has a closed circle, the eyelet, where the fishing wire attaches. The distal end of the shaft curves in a semicircle known as the belly of the fishhook. The belly tapers into a sharp point with a barb. The barb is usually located on the inner surface of the hook, pointing away from the tip. It can also be on outer surface of some hooks. The barb, once pierced through the skin, becomes embedded within the tissue and prevents removal of the fishhook. Additional barbs may be located along the shaft of the fishhook.

INDICATIONS

Any embedded fishhook must be removed from the body. There is no reason a fishhook should not be removed by the Emergency Physician if no contraindication exists.

CONTRAINDICATIONS

There are no absolute contraindications to fishhook removal. Occasionally, the procedure should be referred to a consultant. Globe perforation, globe laceration, and eyelid perforation require emergent consultation with an Ophthalmologist.^{10,11,13,14,18} Place the patient supine with a shield, not a patch, over the eye. Please see Chapter 193 for the complete details regarding eye patching and eye shields. **Penetration of, or near, vital structures (e.g., the neck, groin, or major neurovascular structures) should be given consideration for the appropriate surgical consultation prior to removal of the fishhook.**

FIGURE 124-1. Anatomy of a fishhook.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 3 mL syringe armed with a 25 gauge needle
- Wire cutter
- Needle driver
- Hemostat
- 18 gauge needle
- #11 scalpel blade on a handle
- String, fishing line, or a strong silk tie, at least 50 cm in length
- Tongue depressors
- Safety glasses/goggles or a face mask with an eye shield

The wire cutter and string need to be “clean” and not sterile. The patient’s skin as well as the fishhook were probably dirty and contaminated when the hook penetrated the skin. Wipe the wire cutters with alcohol before and after using it to remove the fishhook.

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Ask the patient to describe the type of fishhook embedded, especially in regard to the number and location of the barbs. Ask the patient to draw a picture of the fishhook or provide you with a similar one to examine. The number and location of the barbs will help in determining the appropriate removal technique. Obtain a signed consent form prior to beginning the procedure. Cleanse the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin surrounding the embedded fishhook and allow it to dry. **The Emergency Physician should wear eye protection when removing a fishhook to prevent injury to their eyes.** At minimum, wear safety glasses or goggles. If available, a facemask with an eye shield is preferred.

TECHNIQUES

PULL-THROUGH TECHNIQUE

This is the traditional method that is used for larger sized hooks embedded in the soft tissue with the barb near the skin surface. This is the preferred technique for fishhooks embedded in the ear, a joint, or the nasal cartilages. Experienced fishermen often perform this

technique in the field, as they would hate to lose prime fishing time to go to the Emergency Department.

Identify the barbed end of the fishhook located under the skin surface. Inject 0.5 to 1.0 mL of local anesthetic solution into the subcutaneous tissue overlying the barbed end of the fishhook to raise a skin wheal (**Figure 124-2A**). Allow 3 to 4 minutes for the local anesthetic solution to take effect. Grasp the shaft of the fishhook with a needle driver (**Figure 124-2B**). Advance the fishhook until the barbed end protrudes through the anesthetized skin (**Figure 124-2B**). **Securely clamp a hemostat over the barb.** This will prevent it from becoming a projectile when cut and injuring someone. Cut the belly of the fishhook just proximal to the barbed end with a wire cutter (**Figure 124-2C**). Grasp the shaft of the fishhook with the needle driver and withdraw it along its direction of entry (**Figure 124-2D**).

Occasionally, fishhooks may have additional barbs on the shaft or the belly (**Figure 124-3**). Inject 0.5 to 1.0 mL of local anesthetic solution into the subcutaneous tissue overlying the barbed end of the fishhook (**Figure 124-3A**). Allow 3 to 4 minutes for the local anesthetic solution to take effect. Grasp the shaft of the fishhook with a needle driver (**Figure 124-3B**). Advance the fishhook until the barbed end protrudes through the anesthetized skin (**Figure 124-3B**). Continue to advance the fishhook until all the barbs on the belly and shaft are below the skin surface (**Figure 124-3B**). Securely clamp a hemostat over the proximal shaft of the fishhook (**Figure 124-3C**). Cut the shaft of the fishhook at the level of the skin with a wire cutter (**Figure 124-3C**). Grasp the fishhook just proximal to the barbed end with the needle driver and pull the remainder of the fishhook out of the tissues (**Figure 124-3D**).

BARB-SHEATH TECHNIQUE

This method is reserved for small fishhooks embedded near the skin surface.¹⁵ This technique should not be used for fishhooks in or near the eye, eyelids, ear, nose, or a joint cavity. Inject 0.5 to 1.0 mL of local anesthetic solution to form a wheal subcutaneously around the area where the fishhook enters the skin. Insert an 18 gauge needle along the entrance wound and aimed toward the barb (**Figure 124-4A**). The bevel of the needle should face the barb with the goal being to engage and cover the barb. Advance the needle and engage the barb in the core of the needle (**Figure 124-4B**). Gently twist and pull the hook back through the entrance wound while the needle covers the barb (**Figure 124-4C**).

An alternative method is to insert a #11 scalpel blade through the anesthetized skin and parallel to the shaft of the fishhook at the site

FIGURE 124-2. The pull-through technique for fishhook removal. **A.** Subcutaneous anesthetic is placed over the barb. **B.** The fishhook is advanced until the barb protrudes from the skin. **C.** A hemostat is placed over the barb before it is cut off with wire cutters. **D.** The fishhook is removed.

FIGURE 124-3. An alternative pull-through technique for the removal of a multibarbed fishhook. **A.** Subcutaneous anesthetic is placed over the barb. **B.** The fishhook is advanced, the distal barb has protruded through the skin, and additional barbs are under the skin. **C.** The shaft is cut. **D.** The fishhook is removed.

it enters the skin. Advance the scalpel blade until it is adjacent to the barb. Withdraw the fishhook and scalpel through the tract. The barb will be resting against the scalpel blade and not get embedded in the subcutaneous tissues. This method is not recommended due to the blind insertion of a scalpel blade into the soft tissues and the potential for secondary injury.

STRING-YANK TECHNIQUE

This method has been extensively described and is often performed by experienced fishermen in the field. It is rapid, effective, and easy to perform; requires fewer repeat attempts; and is relatively painless.¹² This technique should not be used for fishhooks in or near the eye, eyelid, ear, nose, or a joint cavity. **The Emergency Physician should take caution for themselves, the patient, and bystanders. The hook often forcibly flies out of the patient. Ensure the suspected path of the fishhook is clear. Eye protection is recommended with this technique for both the Emergency Physician and the patient.**

Place the body part that the fishhook entered firmly on a flat surface. Local anesthetic solution can be infiltrated, at the Emergency Physician's discretion, into the area where the fishhook enters the skin. Wrap the midpoint of a long string around the belly of the fishhook at the site it enters the skin (**Figure 124-5A**). The string ends should be firmly wrapped around and secured to the index and middle fingers of the Emergency Physician's dominant hand. Use the gloved nondominant thumb or index finger to firmly depress the shaft of the fishhook against the skin until slight resistance is met (**Figure 124-5B**). The shaft should be parallel to the skin and touching the skin. This will disengage the barb from the soft tissues. Quickly and firmly jerk the string (**Figure 124-5C**). This maneuver will release the fishhook from the subcutaneous tissues and pulls it out through the entry wound.

Alternatively, the Emergency Physician may use two tongue depressors to provide secure traction to the string. Wrap each end of the string around one tongue depressor. Instruct an assistant to gently depress the fishhook shaft against the skin while the Emergency Physician jerks the string.⁶

AFTERCARE

The wound should be cleaned of any blood and a dry dressing applied. Administer tetanus prophylaxis if the immunization history is not up-to-date. A radiograph is indicated if there is any suspicion of a retained foreign body. Acetaminophen or nonsteroidal anti-inflammatory drugs will provide any required analgesia. Instruct the patient to clean the area with warm soapy water three times a day and to keep the wound covered until healed. Instruct the patient as to the signs of infection. They should return to the Emergency Department, or their physician, if signs of an infection develop. Routine follow-up is often not required unless the fishhook penetrated the ear, nose, or a joint.

Antibiotic prophylaxis remains controversial.^{1,2,16,17} The use of antibiotics is left to the discretion of the Emergency Physician and should include consideration for the anatomic site of injury, depth of penetration, evidence of gross contamination, and factors that may compromise the patient's immunity (e.g., diabetes mellitus, HIV infection, steroid use, or malignancy). If antibiotic prophylaxis is chosen, prescribe a broad-spectrum antibiotic such as trimethoprim-sulfamethoxazole or doxycycline. These will provide good coverage against gram-negative organisms typically associated with water recreation injuries, as well as some coverage against methicillin-resistant *Staphylococcus aureus* and other community-acquired infections.⁷ Adding ciprofloxacin for *Pseudomonas* coverage may also be considered, as *Pseudomonas* and its subtypes (i.e., specifically *Aeromonas*) are commonly found in soil and freshwater.^{6,16}

FIGURE 124-4. The barb-sheath technique for fishhook removal. **A.** Insert the needle through the entrance wound and aimed toward the barb. **B.** Advance the needle through the entry site to catch the barb in the core of the needle. **C.** The needle and fishhook are removed as a unit.

FIGURE 124-5. The string-yank technique for fishhook removal. **A.** A string is wrapped around the belly of the fishhook. **B.** The shaft of the fishhook is depressed until resistance is encountered. The shaft should be parallel to the skin and touching the skin. **C.** A quick tug on the string will remove the fishhook.

COMPLICATIONS

Complications include infection or damage to the surrounding tissue. Infection is often due to either the contaminated fishhook inoculating the tissues or the fishhook penetrating contaminated skin. Using proper removal techniques will minimize, but not eliminate, any damage to the soft tissues.

Use caution when extracting fishhooks to avoid secondary injury to bystanders, the patient, or the Emergency Physician. Protective eyewear should be worn with all the techniques of fishhook extraction. Ocular injury has been reported to occur during this procedure.² Fishhooks have been surgically extracted from the hypopharynx and the intestine.^{8,9,19} A surgical face mask with a face shield is another mode of protection that the author recommends. When using the pull-through technique, clamping a hemostat to the exposed portion of the fishhook that is to be cut off will prevent flying shrapnel.

SUMMARY

Fishhook removal can be accomplished by one of several simple techniques. It can be performed in the Emergency Department, the office, or the field with minimal supplies. Almost painless removal is possible in most cases without anesthesia. This procedure is gratifying both for the patient and the Emergency Physician.

TASER Probe Removal

Myles McClelland, Alfred Coats III, and Thuy Nguyen

INTRODUCTION

Projective electronic control devices or conductive electrical weapons are commonly known as "TASER" (Thomas A. Swift's Electric Rifle) devices (**Figure 125-1**). They are often used by law enforcement and civilians as a less than lethal alternative to subdue individuals. These devices are deployed at an estimated rate of 904 times per day or approximately one every 2 minutes (personal communication, Steve Tuttle, TASER Int.). TASER devices are estimated to have saved individuals from serious injuries and death from guns and hand-to-hand combat. The devices prevent injury and death of law enforcement officers.¹ These devices are currently used in 107 countries throughout the world. They work by delivering a high-voltage, low-amperage electric shock that affects the motor and sensory functions of the nervous system.²

There are currently no U.S. Occupational Safety and Health Administration (OSHA) guidelines for TASER probe removal. This leaves protocols to be established by individual agencies, Emergency Departments (EDs), Emergency Physicians, and hospitals. The protocols vary. **Treat all probes that have penetrated the skin as biohazards. Follow OSHA standard universal precautions when handling and removing the probes.**

A

B

C

D

FIGURE 125-1. Different models of conducted electrical weapons. (Photos courtesy of TASER Int.)

ANATOMY AND PATHOPHYSIOLOGY

The electric shock is delivered through barbed electrodes that attach to the weapon by conductive wires, penetrates skin and clothing, and disrupts voluntary muscle control. The probe is like a fishhook (**Figure 125-2**). A wire is attached to the proximal end to conduct the electrical charge from the weapon to the probe. The body of the probe is smooth and aerodynamic. The distal end of the probe contains the barb with a reverse hook to maintain itself in a person and not fall out. The barb end contains one or two barbs (**Figures 125-2A and 125-2B**). A new probe was released at the end of 2016 and is available as of 2017.

Blast doors protect the undeployed cartridge. The cartridge contains the probes that are angled away from the center, puncture pin, primer, nitrogen capsule, and the anti-felon identification system (AFID) (**Figure 125-3**). The probes are loaded into the cartridge such that the top probe goes straight and the other probe is at a fixed angle when deployed. The cartridges snap into the weapon. The TASER cartridges are deployed by an electrical arc. The electricity fires a small primer which forces a nitrogen capsule back into a hollow puncture pin. The pin releases the nitrogen into the probe chambers which force the probes out of the cartridge (**Figure 125-4**). The AFID consists of many small pieces of paper with the identity of the cartridge they came from. The pieces of paper are released when the cartridge discharges. The number on the pieces of paper can be tracked by the company to the cartridge

purchaser. Inadvertent deployment can occur from static electricity. There are numerous cartridges that project the probe up to 35 feet accurately (**Table 125-1**). Cartridges for consumers (i.e., not law enforcement) are only available in the 15 foot projection.

FIGURE 125-3. The internal components of the TASER cartridge. (Photo courtesy of TASER Int.)

FIGURE 125-4. The firing of the TASER probes from the cartridge. (Photo courtesy of TASER Int.)

FIGURE 125-5. The firing of an actual TASER weapon. The AFID is seen as colored paper leaving the cartridge. (Photo courtesy of TASER Int.)

Squeezing the trigger on the weapon discharges the electricity into the patient (Figure 125-5). The wires from the weapon to the probes are live when the trigger is squeezed and can result in a shock if touched. The average power output of most devices is approximately 26 W, a current of 2 mA, and a maximum of 50,000 V.^{3,4} The electric current is delivered in 100 millisecond pulses.

The nervous system is an intricate network that communicates via electrical impulses. The peripheral nervous system contains sensory and motor nerves that work in conjunction to communicate information between the brain and musculoskeletal system. This complex circuitry works to control voluntary and involuntary movements. TASER technology mimics these electrical impulses by inhibiting alpha motor neurons and causes involuntary contractions of skeletal muscle. This leads to neuromuscular incapacitation (NMI). There are different levels of NMI ranging from limited area effects to significant body lockup.

The TASER can be used to cause pain in addition to NMI. The pain results from the weapon touching the skin and pressing the trigger. The cartridge must not be in the weapon or it must be deployed for the weapon to be used to cause pain. The local pain that results from touch does not affect the central nervous system and does not cause NMI.

INDICATIONS

All TASER probes require removal. The indications for removal of TASER probes in the ED include patients transported for their removal and probes that are unable to be removed in the field by qualified personnel. Failure to remove the probe in the field may be due to either safety concerns, technical difficulties, or both.

TABLE 125-1 The TASER Probe Spread Varies by the Cartridge Used and the Distance It Travels					
15, 21, and 25 foot cartridges		15 and 25 foot smart cartridges		35 foot smart cartridges	
General: ~1 (0.3 m) feet spread for every 7 feet (2.1 m) of probe travel		General: ~1 (0.3 m) feet spread for every 9 feet (2.7 m) of probe travel		General: ~1 (0.3 m) feet spread for every 14 feet (4.3 m) of probe travel	
Target distance (feet/meters)	Probe spread (in/cm)	Target distance (feet/meters)	Probe spread (in/cm)	Target distance (feet/meters)	Probe spread (in/cm)
2/0.6	4/10	9/2.7	12/31	14/4.3	12/30
5/1.5	9/23	18/5.4	25/64	28/8.5	24/61
7/2.1	13/33	25/7.6	36/92	35/10.6	30/76
10/3.0	18/46				
15/4.5	26/66				
21/6.4	36/91				
25/7.6	38/109				

Source: Modified from information received from TASER Int.

CONTRAINDICATIONS

Contraindications for immediate removal in the field include penetration to critical or vulnerable areas such as the eye, neck, head, female breast, penis, scrotum, and groin.⁵⁻¹³ Injuries to these areas may need further evaluation and consultation prior to removal. Consultation with specialists (e.g., Neurosurgeons, Ophthalmologists, Urologists, or Vascular Surgeons) may be indicated for complicated injuries depending on the location.

EQUIPMENT

- Personal protective equipment
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution (e.g., 1% lidocaine)
- #11 scalpel
- Wound dressings
- Medical pliers
- 3 or 5 mL syringe
- 25 or 27 gauge needle
- 16 or 18 gauge needle

PATIENT PREPARATION

Thoroughly assess the individual for direct and indirect injuries that occurred during and after incapacitation. Examine the entire patient and obtain diagnostic studies if indicated.

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Check the patient's tetanus immune status and update it as necessary.

Place the patient in a position of comfort on a gurney. Expose the area where the TASER probe is embedded. Prepare the area surrounding the probe. Remove any dirt and debris from the skin and the probe. Apply povidone iodine or chlorhexidine solution onto the skin and the probe. Allow this to dry. Don personal protective equipment (i.e., gloves, a gown, a face mask, and eye protection) to prevent exposure to the patient's blood or tissue fluids.

Some patients will tolerate the removal of the probe without anesthetic. This is not recommended. Draw up the local anesthetic agent using sterile technique into the syringe with a large (i.e., 16 or 18 gauge) needle. Switch the needle to a smaller one for patient comfort when administering the local anesthetic solution. Infiltrate the area where the probe enters the skin with 1 to 2 mL of the local anesthetic solution.

TECHNIQUE

The area has been previously cleaned, prepared, and anesthetized. Cut the wires attached to the probe if they are still attached (**Figure 125-6**). Place the nondominant hand on the patient's skin surrounding the probe. Hold the skin taut. Grip the probe firmly with the dominant hand. Medical pliers can be used to grip the probe if unable to grasp it tightly or there are concerns about the possibility of barb injury. Pull the probe perpendicular to the skin in one swift motion. **Take care not to injure yourself or anyone assisting you with the barb.** Hold pressure to site to ensure hemostasis.

The barb may be difficult to remove by manual traction if significant resistance is met. Make a small incision with an #11 scalpel blade. Make the incision down to the level of the barb. **Do not cut any nerves, tendons, or vascular structures.** Most TASER probes

FIGURE 125-6. The TASER probes with attached wires in a person. (Photo courtesy of TASER Int.)

have a channel on the base of the projectile that orients the direction of the barb. Remove the probe from the skin as described above. Clean the area with antiseptic. Irrigate the wound and close the incision with sutures.

ALTERNATIVE TECHNIQUE

An alternative method is like that used for the removal of a fishhook (Chapter 124). Use a 3 mL syringe armed with a 16 or 18 gauge needle. Insert the needle along the channel of the probe with the bevel of the needle facing inward. Cover the barb of the probe with the bevel of the needle. Slowly remove the probe and needle together to prevent the barb from catching in the surrounding tissue. Hold pressure to the area to ensure hemostasis.

ASSESSMENT

The barbed electrodes from a TASER probe are designed to penetrate at a depth of no greater than 4 mm, reducing risks for serious injuries and complications. Assess the patient for any neurologic or vascular damage that occurred from the probe removal. Consult the appropriate specialist if any damage is found.

AFTERCARE

Hold pressure to ensure hemostasis. Clean the area with antiseptic and apply a dressing. Standard wound care should be applied to the affected site. Have the patient monitor the probe site for signs and symptoms of an infection (e.g., erythema, fever, purulence, or tenderness). A wound check in 48 hours is advised for contaminated wounds, difficulty during the removal process, or if there is concern for a retained foreign body. Prophylactic antibiotics are not indicated due to the low risk for significant wound infection.¹⁴

COMPLICATIONS

Rare and significant injuries that have been reported in association with electronic control devices include bone lodgement of the probe, cutaneous burns, lacerations, rhabdomyolysis, testicular torsion, ocular injury, miscarriage, and death.^{6-9,13,15-21}

TASER injuries around the orbits should raise the concern for the possibility of penetrating ocular injury.^{5,7,9,12} Removal of the probe in such areas should not be attempted in the ED due to the likelihood of vitreous loss which may cause the globe to collapse.⁷ A computed tomography (CT) scan of the orbits may be necessary to evaluate the extent of the injury and to identify the location of the barb. Consult an Ophthalmologist for removal of the probe in the Operating Room under general anesthesia.

Treat probes in the neck as penetrating trauma. Perform a careful and prompt assessment to the airway and surrounding vascular structures. Emergent treatment should include airway establishment, hemodynamic monitoring and stabilization, and clarification of the extent of injury per standard advanced trauma life support (ATLS) protocol. Standard treatment protocol remains controversial, but surgical intervention to determine the extent of injury caused by penetrating trauma to the neck remains the gold standard.²² Use angiography in the stable patient to assess any suspicion of vascular injury. Consult a Vascular Surgeon if any signs of injury are noted.

Probes lodged in anatomically sensitive areas (i.e., the female breast, penis, scrotum, and groin) are normally not removed in the field by most prehospital protocols. Injuries to these areas may require local anesthesia, evaluation of surrounding structures, radiographic studies, and a more appropriate setting due to the sensitive location of the injury.

Probe penetration to the head and skull will require further evaluation, radiographic studies, and appropriate consultation in the ED.^{10,11,23} A physical assessment, including a thorough neurologic exam, is necessary to determine if the individual is neurologically intact. Perform a CT scan to determine the extent of penetration and to rule out the possibility of intracranial hemorrhage. Removal of probes that are embedded in the skull or head is not recommended at the bedside in the ED. The removal process should be performed in the Operating Room to ensure that all parts of the probe are adequately removed.

SUMMARY

Law enforcement agencies continue to evolve into using less than lethal means of subduing suspects. There is a growing need for Emergency Physicians to understand the possible complications of these methods. The use of conductive electrical weapons (e.g., the TASER) is becoming more common. These weapons are meant to subdue an individual without causing death, serious injuries, and complications. Health care personnel involved in prehospital care as well as those in the ED should be able to recognize these possible complications in order to manage and provide appropriate care.

Ring Removal

Abraham Berhane, Abdoulie Njie, Robert Needleman, and Steven H. Bowman

INTRODUCTION

The need to remove a ring is not uncommon in the Emergency Department.¹ Patients may present with an initial primary complaint that they can no longer remove a ring or that a ring has become painful. A variety of conditions may necessitate the urgent removal of a ring (e.g., allergic reactions, burns, fractures, increases in total volume status, infection, and swelling from extremity trauma). Swelling of the digit can rapidly progress and cause the ring to become a constricting band and compromise blood flow to the digit (**Figure 126-1A**). Critically ill patients undergoing admission to intensive care settings or emergency surgery may need to have rings removed urgently. **The Emergency Physician's goal is to remove the ring in a timely manner and not cause additional injury.** The information in this chapter applies to rings on the fingers and toes.

ANATOMY AND PATHOPHYSIOLOGY

The second through fourth digits receive their blood supply through four vessels (i.e., palmar radial digital arteries, palmar ulnar digital arteries, dorsal radial digital arteries, and dorsal ulnar digital arteries). The thumb receives its blood supply from the dorsalis pollicis and princeps pollicis arteries. Blood returns from the digits via the dorsal digital veins. Venous return is impeded and swelling ensues when the digit is compressed for prolonged periods by a tight-fitting

A

B

FIGURE 126-1. The tight ring that cannot be removed. **A.** The tight ring with distal finger swelling in an unconscious patient. **B.** After ring removal with a ring cutter. The finger is macerated with an iatrogenic laceration from the ring cutter. (Courtesy of Brian Lin, MD, and www.lacerationrepair.com.)

ring. The swelling results in greater compression and further propagation of this cycle. The increased swelling will eventually impede the arterial supply to the digit in theory.

The greatest circumference of the finger is at the proximal interphalangeal (PIP) joint. **Rings usually become entrapped proximal to the PIP joint.** Skin breakdown and tissue necrosis occur if the constricting ring is not removed. The untreated digit is at risk for infections (e.g., cellulitis, osteomyelitis, and tenosynovitis). The digit viability may be threatened in severe cases. There are several case reports of rings that have become embedded in the soft tissue of the digits.²⁻⁶

Most patients will experience pain and seek medical attention prior to the development of severe complications. Patients with an altered mental status, peripheral neuropathies, peripheral vascular

disease, psychiatric illness, or other chronic disability may present later with complications.^{2,3,5,6}

INDICATIONS

Rings are usually removed to prevent ischemia of a digit. Remove a ring if the digit shows any signs of neurovascular compromise (e.g., decreased capillary refill, decreased pulse wave on pulse oximetry, decreased sensation, mottling, paleness, or paresthesias). Remove rings whenever the patient complains that a ring is causing pain. Rings must be removed from any injured digit where edema is possible (e.g., burns, contusions, crush injuries, fractures, lacerations, and sprains). Remove all rings from the digits on the involved side for any extremity injury above the digits and where edema of the distal extremity is possible. Other nontraumatic conditions that may necessitate emergent ring removal include acute increases in volume status, allergic reactions, and infections of the upper or lower extremity. A patient may present and request a ring be removed that is tight and can no longer be taken off. Consider the need for urgent ring removal with markedly decreased levels of consciousness and in all critically ill patients, particularly those being admitted to intensive care settings or undergoing emergent surgery.

CONTRAINDICATIONS

There are no absolute contraindications to removing a ring. It is important to note that certain techniques may be more applicable than others depending on the individual patient, provider experience, and the ring material.

EQUIPMENT

■ METACARPAL BLOCK

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol swab
- 3 mL syringe
- 25 or 27 gauge needle, 1 inch long
- 3 to 5 mL local anesthetic solution without epinephrine

■ LUBRICANT AND CATERPILLAR TECHNIQUES

- Lubricant (e.g., K-Y jelly, liquid soap, mineral oil, petrolatum, or Surgilube)

■ STRING TECHNIQUE

- String (1–0 silk suture, cotton umbilical string, intravenous tourniquet, Penrose drain, or tracheal tape)
- Mosquito hemostat

■ RUBBER BAND TECHNIQUE

- 3 to 4 mm wide rubber band
- Lubricant (e.g., K-Y jelly, liquid soap, mineral oil, petrolatum, or Surgilube)
- Mosquito hemostat

■ GLOVE TECHNIQUE

- Rubber gloves
- Lubricant (e.g., K-Y jelly, liquid soap, mineral oil, petrolatum, or Surgilube)
- Mosquito hemostat
- Scissors

■ RING CUTTER TECHNIQUE

- Ring cutter, manually operated or battery-powered
- Steinman pin cutter if a ring cutter is not available
- Two large hemostats or needle drivers
- Pliers, optional

■ VICE-GRIP PLIERS TECHNIQUE

- Medium size vice-grip pliers

■ MISCELLANEOUS SUPPLIES

- Ice water
- Penrose drain or intravenous (IV) tourniquet
- Basin or zip-lock bag for ice water

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Document this in the medical record. A signed informed consent is not required for the removal of a ring. Place the patient sitting upright or in a semi-recumbent position. Position their hand on a bedside procedure table. Provide analgesia in the form of a metacarpal block for patients complaining of pain (Chapter 156).

The removal of a tight ring is considered a two-step process. Reduce the edema in the finger and then remove the ring.⁷ Instruct the patient to elevate the affected hand or foot to reduce edema prior to any attempts at ring removal. Use a finger trap to elevate the affected extremity if the patient has difficulty or cannot keep the extremity elevated (**Figure 126-2**). Consider soaking the hand or foot in ice water for 5 to 10 minutes to reduce edema. An elastic bandage, gauze, Penrose drain, or piece of tape can be wrapped around the finger from distal to proximal to further reduce swelling.⁸

The simplest and most effective way to remove a ring from a finger is to cut the ring using a ring cutter. Reassure the patient that most cut rings can be repaired by a jeweler. Patients may still be reluctant to have expensive rings or rings with sentimental value removed with a ring cutter. The Emergency Physician must consider time needed to remove the ring, the individual circumstances regarding the entrapment, the equipment available, which alternative techniques may be effective, and the status of the Emergency Department.^{1,9}

TECHNIQUES

LUBRICANT TECHNIQUE

This technique works for mild cases of ring entrapment with minimal swelling and without significant trauma. Many patients will attempt to remove the ring using some type of lubricant at home prior to presenting to the Emergency Department (**Figure 126-3**). The same technique may be tried in the Emergency Department prior to attempting other techniques. Liberally apply a lubricant (e.g., K-Y jelly, liquid soap, mineral oil, petrolatum, or Surgilube) to the digit and beneath the ring. Attempt to advance the ring over the PIP joint with steady traction.

CATERPILLAR TECHNIQUE

This technique is useful in that it requires no additional materials other than lubricant (**Figure 126-4**).¹⁰ Liberally apply a lubricant to the finger (**Figure 126-4A**). Slide the ring down the proximal phalanx and just proximal to the PIP joint. Apply and maintain upward pressure on the bottom of the ring (**Figure 126-4B**). Simultaneously

FIGURE 126-2. The hand and arm suspended in a finger trap. (Courtesy of Instrument Specialists Inc., Boerne, TX.)

swing the upper portion of the ring distally (**Figure 126-4C**). Pull the top of the ring over the PIP joint. Apply and maintain downward pressure on the top of the ring (**Figure 126-4D**). Simultaneously swing the lower portion of the ring distally to free it (**Figure 126-4E**).

FIGURE 126-3. The use of butter as a lubricant to remove an entrapped ring.

Continue the technique motions to remove the ring from the finger. This “caterpillar motion” allows the ring to be slowly advanced distally and removed. A Kelly clamp can be used to push the ring and gain a mechanical advantage.¹¹

FIGURE 126-4. The caterpillar technique. **A.** The entire finger is lubricated. **B.** The ring has been pushed down the proximal phalanx until it reaches the PIP joint. Push the bottom of the ring up firmly while maintaining pressure. **C.** Swing the top portion of the ring distally over the joint while maintaining upward pressure. **D.** Push down firmly while maintaining downward pressure. **E.** Swing the bottom portion of the ring proximally over the joint and remove the ring.

STRING TECHNIQUE

Several authors have extensively described the string technique and its modifications (**Figure 126-5**).^{5,7,12-14} This technique consists of using a “string” to compress the edematous tissue, exsanguinate the digit, and facilitate the passage of the ring over the PIP joint. Avoid this technique if the patient has an embedded ring, an associated finger fracture, or an associated finger laceration.^{12,15}

Pass a length of 1–0 silk suture or a piece of string underneath the ring (**Figure 126-5A**). Avoid monofilament sutures and smaller-size sutures as they may break or inadvertently cut the patient if wound too tightly. Passage of the string or suture may be facilitated with the use of a mosquito hemostat.^{12,15,16} Wind the distal portion of the suture tightly around the digit in a closed spiral (**Figure 126-5B**). **There should be no interposition of skin between the turns of the suture material to ensure even compression of the skin and soft tissue.** Continue the spiral distally to just beyond the PIP joint. Grasp the proximal end of the suture. Unwind the suture while maintaining traction in the distal direction (**Figure 126-5C**). The ring will be pushed distally as the suture unwinds. The ring is easily removed once it clears the PIP joint (**Figure 126-5D**).

Other materials (e.g., cotton gauze, oxygen mask straps, Penrose drains, rubber intravenous tourniquets, surgical mask ties, or umbilical tape) have been used instead of string.^{7,13,14,17-20} These materials have certain practical advantages. They require fewer turns and shorter lengths to encircle the finger because they are wider than suture. It is easier to wind these materials around the digit without interposition of the skin between the turns (**Figure 126-6**).

Insert the umbilical tape under the ring from distal to proximal with the aid of a mosquito hemostat (**Figure 126-6A**). Pull 6 to 7 cm of the umbilical tape proximal to the ring (**Figure 126-6B**). Wind

FIGURE 126-5. The string technique. **A.** A string is passed between the ring and the finger. **B.** The string distal to the ring is wound tightly around the finger and continued distally to the level just below the PIP joint. **C.** The string proximal to the ring is slowly unwound and moves the ring distally. **D.** When the ring passes the PIP joint, it usually comes off without effort.

FIGURE 126-6. The string technique with umbilical tape. **A.** The umbilical tape is inserted under the ring with a mosquito hemostat. **B.** The umbilical tape is pulled through to the other side of the ring. **C.** The umbilical tape distal to the ring is wound tightly around the finger to the level just below the PIP joint. **D.** The umbilical tape proximal to the ring is slowly unwound and moves the ring distally. **E.** The ring passes the PIP joint. **F.** The ring is free and usually comes off without effort.

the distal portion of the umbilical tape tightly around the digit in a closed spiral (**Figure 126-6C**). There should be no interposition of skin between the turns of the umbilical tape. Continue to spiral distally to just beyond the PIP joint (**Figure 126-6C**). Grasp the proximal end of the umbilical tape. Unwind the proximal end of the umbilical tape while maintaining traction in a distal direction (**Figure 126-6D**). Continue to unwind the umbilical tape until the ring passes the PIP joint (**Figure 126-6E**). The ring is easily removed once it clears the PIP joint (**Figure 126-6F**).

This technique may be slower than using a ring cutter. It does assure the integrity of the ring and minimizes the potential risk of patient injury that may occur with use of certain commercial devices (e.g., the locking pliers for removal of tungsten carbide rings).¹³

RUBBER BAND TECHNIQUE

This technique uses a 3 to 4 mm wide rubber band to apply traction on the ring and facilitate its passage over the PIP joint in a safe

FIGURE 126-7. The rubber band technique. **A.** A mosquito hemostat is passed below the ring and grasps the rubber band. **B.** The rubber band is pulled beneath the ring and out the other side. **C.** The rubber band is positioned with equal lengths of loop on each side of the ring. **D.** Both loops of the rubber band are grasped and pulled distally while it is simultaneously rotated circumferentially. **E.** When the ring passes the PIP joint, it usually comes off without effort.

and efficient manner (**Figure 126-7**).^{16,21} Success has been reported using rubber bands. Reserve this technique for less severe ring entrapments. Avoid this technique if the patient has an embedded ring, a fracture, or a laceration.

Lubricate the finger liberally. Pass the rubber band beneath the ring using a mosquito hemostat (**Figures 126-7A and 126-7B**). Position the rubber band so that equal lengths are on each side of the ring (**Figure 126-7C**). Insert a finger through both loops of the rubber band (**Figure 126-7D**). Pull the loops of the rubber band distally while simultaneously moving them circumferentially between the ring and the finger (**Figure 126-7D**). Continue the motion until the ring is removed (**Figure 126-7E**).

GLOVE TECHNIQUE

This technique has been advocated for use in patients with underlying soft tissue injury to the finger.^{22,23} Its success is anecdotal. The glove technique uses a finger cut from an appropriately sized rubber glove (**Figure 126-8**). The glove finger acts as a barrier to protect damaged soft tissue, provides a “leading edge” to guide the ring over the damaged tissues, and provides mild compression. The glove technique may be no more effective than any other in cases of severe finger edema despite these theoretical advantages.

Choose a glove that fits the patient snugly. Use the patient’s other hand to aid in choosing the right size glove. Cut the finger from a glove to match the finger of the patient (**Figure 126-8A**). Cut off the tip of the finger of the glove to create a cylinder (**Figure 126-8A**). Slide the cylinder onto the patient’s finger. Advance the proximal

FIGURE 126-8. The latex glove technique. **A.** The finger matching the one on which the ring is lodged is cut from an examination glove. **B.** The latex cylinder is put on the finger. The proximal edges of the cylinder are pulled under and proximal to the ring using a mosquito hemostat. **C.** The proximal edges of the latex cylinder are slowly pulled distally to roll the ring off the finger.

portion of the cylinder beneath the ring using a mosquito hemostat (**Figure 126-8B**). Lubricate the cylinder and the ring (e.g., K-Y jelly, liquid soap, mineral oil, petrolatum, or Surgilube). Pull the proximal edges of the latex cylinder distally with fingers or mosquito hemostats to advance the ring distally (**Figure 126-8C**). Continue to pull on the proximal cylinder until the ring moves past the PIP joint and falls off the finger.

RING CUTTER TECHNIQUE

The definitive method for ring removal is cutting the ring. Cut the ring if the patient presents with an embedded ring, entrapment with nonjewelry items, severe swelling, or an underlying injury. Cutting a ring is generally rapid and safe. A ring cutter can be used to cut rings made of gold, plastic, platinum, silver, stainless steel, and titanium.

Many devices will cut rings. The standard rotary ring cutter should be available in every Emergency Department (**Figure 126-9**). Inspect the ring cutter blade periodically to ensure that it is sharp. Battery-powered ring cutters are available (**Figure 126-10**). The advantages of the powered ring cutter are that they can easily cut nonjewelry items, do not rely on strength, and are easy to use, fast, lightweight, and powerful. The Steinman pin cutter has been used successfully in the absence of a ring cutter to cut rings (**Figure 126-11**).²⁴ A sharp pair of diagonal pliers can be effective to cut small rings.

FIGURE 126-10. The GEM Ring Cutting System (Mooney & Co., Ashland, OR). A battery-powered and motorized ring cutter.

Pass the finger guard of the ring cutter between the ring and the digit at the thinnest part of the ring (**Figure 126-12**). **Use care to place the ring cutter correctly and avoid additional injury.** Squeeze the ring using a heavy needle driver, hemostat, or pliers to change its shape from round to oval to facilitate passage of the finger guard (**Figure 126-13**). This additional distortion of the ring will not further exacerbate the entrapment.²⁴ Lower the cutting blade onto the ring. Turn the turn key to rotate the blade while maintaining pressure on the ring (**Figure 126-14**). Continue turning the turn key until the blade completely cuts through the ring. Pry the ring open with two hemostats, needle drivers, or pliers once it is completely cut through and remove the ring (**Figure 126-15**).²⁵ An alternative to one cut and prying the ring open is to make two cuts on opposite sides of the ring so that it falls apart in two pieces.

Irrigate any open wound (**Figure 126-1B**) with normal saline to remove any small metal fragments that may result from the cutting process. There is a case report of a foreign body granuloma caused by metal particles left in a finger wound following ring removal.²⁶

VICE-GRIP PLIERS TECHNIQUE

Many rings cannot be removed with the previously described techniques.²⁷ These rings can be of a material that cannot be cut with a carbide, diamond, or metal cutting disk on a ring cutter. This includes rings made of ceramics, natural stone (e.g., jade or onyx), and tungsten carbide. These rings can be removed by cracking them into pieces in a controlled fashion using a vice-grip pliers.^{13,28}

A medium-sized vice-grip pliers is usually appropriate for most ring sizes. Open the jaws of the vice-grip pliers. Adjust the tightening screw so that the closed jaws of the vice-grip fits over the ring (**Figure 126-16**). Close and clamp the vice grip so that the jaws close lightly on the ring. Release the jaws, turn the tightening screw one-quarter of a turn, and reclamp the jaws on the ring. Continue

FIGURE 126-11. The Steinmann or orthopedic pin cutter.

FIGURE 126-12. Ring removal using a manual ring cutter.

this process of releasing the jaws, turning the tightening screw one-quarter of a turn, and reclamping the jaws on different places of the ring each time until a crack is heard. Keep continuing this process of tightening the jaws and reclamping different areas of the ring until the ring breaks into pieces and falls off.

Tungsten carbide rings are an important consideration due to their increasing popularity. These rings are inexpensive and bought from all over (e.g., Internet). **It is difficult to remove these rings with traditional ring-cutting devices due to inorganic compounds that make them extremely hard.** Tungsten carbide is the hardest material used to make jewelry. It cannot be cut or even scratched by instruments routinely in the Emergency Department. **The brittle nature of the material makes tungsten carbide amenable to removable with the vice-grip pliers.**^{13,29} Removal techniques using string, umbilical tape, or vice-grip pliers are effective at removing tungsten rings.¹³ Use of a vice-grip plier was more efficient (i.e., 23.1 vs. 135.4 seconds) at the expense of destroying the ring.¹³ Potential complications to consider include superficial lacerations and retained debris within any potential wound.²⁹

FIGURE 126-13. A pair of pliers is used to make the ring "oval" in shape. This may facilitate the use of a ring cutter.

FIGURE 126-14. Cutting a ring with the manual ring cutter (left). The ring is pried off (upper right) and the finger is released (lower right).

ALTERNATIVE TECHNIQUES

Patients may rarely present with other heavy circular objects on their digits (e.g., nuts, steel rings, or washers) that cannot be removed using a manually operated ring cutter. Powered cutting tools such as heavy-duty saws and bolt cutters may be needed to remove these objects. Battery-powered ring cutters may be ideal in these situations. Power saws and Dremel tools with carbon blades have been used to successfully remove hardened steel rings from fingers.^{6,30,31} Case reports exist of the use of dental saws or dental drills for the same purpose.³²⁻³⁵ **Use care if it becomes necessary to use a powered metal cutting device to protect the patient from secondary injury from the cutting element and from thermal injury associated with the heat generated by these powered devices.** Keep the

finger wet to reduce friction-associated heat and thermal injury from electric saw equipment.³⁴

Another technique uses the elastic strap from a nonbreather mask.¹⁴ Wrap the elastic strap around the finger from distal to proximal until reaching the ring. Push the tail of the strap under the ring toward the hand. Allow time for the edematous tissue to be compressed by the elastic band. Unwind the elastic band starting at the top of the hand toward the tip of the finger, moving the ring over the PIP. The pain from compression can be mitigated by a digital block.

ASSESSMENT

Thoroughly examine the finger for any injuries after the ring is removed (**Figure 126-1B**). Reassess perfusion to the digit by noting the capillary refill time, color, and pulse oximeter readings on the affected digit compared to adjacent fingers.

FIGURE 126-15. Prying open a cut ring.

FIGURE 126-16. A vice-grip pliers can be used to remove hard or brittle rings.

AFTERCARE

No specific aftercare is required following the ring removal process. Elevation, nonsteroidal anti-inflammatory drugs (NSAIDs), and local wound care are all that is necessary. Consultation with a Hand Surgeon, Orthopedic Surgeon, Plastic Surgeon, or Podiatrist is recommended in severe cases that include embedded rings, infections, neurologic compromise, or vascular compromise. The aftercare is based on any lacerations and/or fractures of the digit. Determine the patient's tetanus immune status and administer the appropriate prophylaxis if the skin is broken. Instruct the patient not to place any rings on the digit until the edema has completely resolved. Place the ring, and any pieces, in a specimen container and return it to the patient. A jeweler can later fix most rings.

COMPLICATIONS

The direct complications of ring removal are minor compared to the complications that may occur from failure to remove a ring. Direct complications include secondary injury (i.e., to nerves, soft tissues, and vascular structures) and granuloma formation. This can be due to passing objects and instruments under an extremely tight ring or from improperly used instruments to remove the ring. Ring fracture compression techniques (i.e., vice-grip pliers) that require large amounts of pressure for removal have been found to be a safe methodology when indicated.¹³

Ring cutters have their own specific issues. It may cut too slowly. Ensure that the proper cutting technique is being used. The cutting disk may be dulled or the wrong cutting disk for the material. Check that the proper cutting disk is on the ring cutter and that it is not dull or worn. Install fresh batteries or recharge them to maximize the power of the electric ring cutter. The ring and the patient's finger can become quite hot and burnt.³⁶ Periodically check the progress and make sure that the ring has not been cut and is now cutting the finger guard. Using a cutting disk that is dull, worn, or incorrect can generate significant heat. Correct these issues. Submerge the finger in ice water for a few minutes and then resume cutting the ring.

SUMMARY

Ring removal is a relatively straightforward and simple procedure. A variety of potential approaches may assure success. Use of the ring cutter is the most reliable and quickest technique. Base the decision to use a ring cutter upon the urgency with which the ring must be removed and not upon the monetary or sentimental value of the ring. Direct compression techniques may increase in implementation as the popularity of titanium and tungsten rings grow. Formal ring removal algorithms exist.³⁴ Implement the techniques that are most familiar to achieve safe and timely results.

Subungual Hematoma Evacuation

Steven H. Bowman, Neera Khattar, and Natasha Thomas

INTRODUCTION

The fingers and toes are two of the most commonly injured areas of the body. The distal ends of these digits (i.e., the nail apparatus) are especially prone to injury. Digital injuries include amputations, avulsions, contusions, crush injuries, fractures, and lacerations.

FIGURE 127-1. A subungual hematoma. (Courtesy of Path Scientific LLC, Carlisle, MA.)

The most common injuries to the distal fingers and toes are crush injuries (e.g., closure of a door and dropped objects). Digital injuries occur when the distal aspect of the finger or toe is caught between two objects and typically involves a large amount of force.

Subungual hematomas often develop following blunt or crush injuries to the distal fingers or toes (**Figure 127-1**).¹⁻³ Hematomas can form from repetitive mild trauma to the digits (e.g., running while wearing tight shoes). These injuries cause accumulation of blood between the nail and the nail bed and result in a subungual hematoma (**Figure 127-2**). Treatment of a subungual hematoma is relatively straightforward, yet in some cases, it is still controversial. It is important to understand the structure of the distal finger or toe (**Figure 127-3**) to determine whether drainage alone will be sufficient management and to also consider how initial management may affect outcome.

ANATOMY AND PATHOPHYSIOLOGY

The nail apparatus is a complex structure composed of multiple components (**Figure 127-3**). The nail plate is a keratinized structure that overlies the nail bed and matrix.⁴ It is curved on three edges to allow it to embed into the surrounding soft tissues. The perionychium is composed of the nail bed and the surrounding soft tissue. The hyponychium is the junction of the nail bed at the sterile matrix and the fingertip skin beneath the distal margin of the nail. The eponychium is the distal portion of the nail fold where it attaches to the proximal surface of the nail plate. The matrix is visible in the proximal portion of the nail as a white half-moon structure known as the lunula.

The nail bed consists of the germinal matrix on the proximal ventral floor of the nail fold and the sterile matrix extending from the

FIGURE 127-2. The subungual hematoma. **A.** Surface view. **B.** Sagittal view.

FIGURE 127-3. The anatomy of the distal fingertip and nail bed. **A.** Surface anatomy. **B.** Midsagittal view.

lunula to the hyponychium.⁴ It was originally thought that the germinal matrix is primarily responsible for the growth of the nail, with a significant contribution from the sterile matrix.^{5,6} It is now known that the entire nail bed contributes to the growth and migration of the nail plate.⁴ The nail bed must be smooth for normal nail growth. A nail matrix that has not been well approximated to minimize scar formation may develop a deformed nail.³⁻⁹ Trauma to the matrix can cause nail deformities, leading to poor cosmetic and functional outcomes.

The nail bed receives its blood supply from terminal branches of the proper palmar or volar digital artery, which communicate to form blood sinuses.⁴ Venous drainage involves a combination of the superficial and deep venous systems that begin at the proximal portion of the nail bed and the skin proximal to the nail fold.⁵ Injuries to the distal ends of the fingers and toes disrupt the vascular structures and cause compression of the capillaries located between the distal phalanx and the nail plate (**Figures 127-1 and 127-2**). The blood collection that results is known as a subungual hematoma. **The hematoma appears as a black-and-blue or black-and-purple area under the nail that is extremely tender to palpation.**

Nailbed injuries may be classified as avulsions, crush injuries, lacerations, and stellate lacerations.^{1,6} Each of these types of nail bed injuries may result in a subungual hematoma. It is important to recognize how painful subungual hematomas are due to the pressure from the hematoma. The injury also causes pain.

The management of subungual hematomas is still somewhat controversial. The approach to management was initially very aggressive, since subungual hematomas are often seen with fractures of the distal phalanx, damage to the nail, and damage to the

nail apparatus.^{1,2,5-9} The surgical literature generally recommends removal of the nail plate, inspection of the nail bed, and repair of any nail bed injury if the subungual hematoma involves 25% or more of the nail surface.^{1,2,5-10} This practice has been questioned by controlled studies that demonstrated excellent outcomes in patients with large (i.e., greater than 25%) subungual hematomas treated by trephination alone, regardless of the presence of fractures.^{6,10-13} Larger hematomas involving over 50% of the nail surface may be treated successfully with trephination. Many authors, primarily Hand Surgeons, still advocate the removal of the nail plate to thoroughly inspect the nail bed and effect repair in all patients who present with a subungual hematoma. Although this approach is time-honored, studies have demonstrated that nail plate removal is not necessary if it is still attached to the matrix, even in the presence of a distal phalanx fracture.^{12,13} Trephination alone results in significant cost savings.^{13,14}

PHYSICAL EXAMINATION

Thoroughly examine the injured digit prior to drainage of a subungual hematoma. Examination involves inspecting the hematoma to assess the approximate size or percentage of the nail involved. Assess the nail plate for any other injuries. Perform a complete neurologic exam including motor and sensory function. Assess extensor and flexor tendon function. Some patients with a nail bed injury may require a digital nerve block prior to examination. This will blunt the motor and sensory assessments. Capillary refill time can be used to determine vascular function in the injured digit.

IMAGING

The utility of imaging in patients with subungual hematomas is controversial. Some studies advise a complete set of radiographs to rule out foreign bodies and fractures. Other studies have shown that imaging can be avoided in patients with complete resolution of their pain with trephination alone. Most distal phalanx fractures have a low rate of complications, have a low yield for positive imaging, are nondisplaced, and are simple distal phalanx fractures. Using ultrasound to assess for significant soft tissue injuries or distal phalanx fractures is becoming more popular in the Emergency Department (Chapter 100). The use of ultrasound may become a recommended form of imaging in the future.^{15,16}

INDICATIONS

Patients who present to the Emergency Department after sustaining an injury with a resultant subungual hematoma will generally complain of severe pain. Trephination (i.e., the process of making a small hole in the nail plate to allow collected blood to drain) will result in significant pain relief for most patients.^{2,10} Use trephination when the patient presents with a painful subungual hematoma and an intact (i.e., not fractured or avulsed) nail plate that is still attached to the matrix.^{13,14,17,18} Treatment may be more complicated than simple trephination if the nail plate is partially or completely avulsed from the matrix.^{13,16,18} Trephination can be avoided in favor of conservative management with a protective splint and analgesia if the hematoma is not causing the patient significant pain or discomfort.

CONTRAINDICATIONS

Simple trephination is reserved for patients with intact nails and nondisplaced distal phalanx fractures. **Patients who present with nail plate fractures, avulsions of the nail plate, disruption of the nail margin, or partial amputations may require more extensive therapy with removal of the nail plate and repair of the nail bed**

(Chapter 129).¹³ Avoid trephination using heat-based methods in patients wearing artificial nails due to the potential for igniting the nail or nail adhesive.²⁰ **Subungual hematomas that extend proximal to the nail bed often represent proximal nail plate avulsions or injuries that require nail plate removal, nail plate repair or reinsertion, and nail bed repair.**

The lack of trauma is a concern if the patient has no recollection of trauma to the digit. The subungual hematoma is usually the result of a traumatic injury. A spontaneous subungual hematoma can be seen with subungual Kaposi's sarcoma, subungual melanoma, and other systemic diseases. Refer all spontaneous subungual hematomas to a Dermatologist.

EQUIPMENT

DIGITAL OR METACARPAL BLOCK

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- 3 mL syringe
- 25 or 27 gauge needle, 1 inch long
- Local anesthetic solution without epinephrine

ELECTROCAUTERY

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- Battery-powered electrocautery device

PAPER CLIP TECHNIQUE

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- Heat source (i.e., open flame)
- Paper clip or safety pin
- Hemostat

DRILL TECHNIQUE

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- 18 gauge needle
- Cotton-tipped applicators

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Consider obtaining radiographs for significant traumatic injuries, suspected associated fractures, or any injury where the nail plate is damaged or avulsed. Place the patient in a sitting or semirecumbent position on a gurney or multipositional procedure chair. Sit facing the patient.

Place the hand with the injured digit palm side down on a flat surface. Cleanse the injured digit of any blood, dirt, and debris. Apply povidone iodine or chlorhexidine solution over the nail plate and allow it to dry. An alcohol swab is an alternative to these solutions. **Always allow the alcohol to dry before touching the nail plate with a hot object so that the alcohol does not ignite.** Copiously irrigate the affected digit to remove any debris and reduce the likelihood of an infection. Studies have shown that copious irrigation has more success in preventing infection than prophylactic antibiotics.²¹

FIGURE 127-4. The battery-operated electrocautery device.

A digital block is generally not needed if using heat-based methods to penetrate the nail plate.^{2,6,10,13,14,20,22} The nail plate is not innervated and the hematoma prevents contact with the nail bed. A digital block may be required if the patient is excessively anxious, if additional injury is present, or if a drill technique is to be performed (Chapter 156). An alternative to the digital block is to soak the affected finger in ice water for a few minutes prior to the procedure. The techniques described below may be used on fingernails and toenails.

TECHNIQUES

ELECTROCAUTERY TECHNIQUE

Electrocautery is an efficient technique to drain a subungual hematoma. Battery-operated microcautery devices are generally available in the Emergency Department (**Figure 127-4**). **Assure the patient that they will not be burned.** Stabilize the injured digit proximally with the nondominant hand. Grasp the cautery unit like a pencil with the dominant hand. Press the button on the cautery unit to heat the tip. Release the button and allow the tip to cool for 1 to 2 seconds. This may prevent penetrating the nail plate too quickly and damaging the underlying nail bed. Place the hot tip on the nail plate, centered over the hematoma (**Figure 127-5**). **Tap the nail plate several times with the cautery pen tip. Do not constantly hold the hot tip against the nail plate.** The cautery tip will easily penetrate the nail plate and a “give” is typically felt. **Do not plunge the cautery pen tip into the subungual hematoma to avoid injuring the nail bed and/or causing additional pain.**

Darkened blood will flow out of the hole when the hematoma is entered. The nail will regain its normal color after the hematoma is drained. Apply slight digital pressure to the nail plate to ensure complete drainage of the hematoma. “Milk” the blood out the hole(s) made in the nail plate. The patient will usually begin to feel pain relief at this point.

The tips of some microcautery devices are shaped in such a way that they will not make a hole that is wide enough to allow adequate drainage. Slightly rotate the cautery unit as it traverses the nail plate to ensure an adequate sized drainage hole of 3 to 4 mm. Some physicians prefer to make an additional hole in the nail plate to ensure drainage

A

B

FIGURE 127-5. The electrocautery technique. The hot tip of the unit is centered over the subungual hematoma and allowed to penetrate the nail plate. **A.** Artist illustration. **B.** Using the device on a patient. if the first hole becomes occluded. As an alternative to the single large hole, place three to four smaller drainage holes in the nail plate.

PAPER CLIP TECHNIQUE

This technique is similar to using the electrocautery unit. Unfold and heat the tip of a paper clip or safety pin with a flame from a lighter or alcohol lamp. **Ensure that any alcohol used to clean the nail plate completely dries before attempting the paper clip technique.** Place the heated tip of the paper clip against the nail plate and centered over the subungual hematoma (**Figure 127-6**). Apply slight downward pressure to allow the heated paper clip to perforate the nail plate. **Do not plunge the cautery pen tip into the subungual hematoma to avoid injuring the nail bed and/or causing additional pain to the patient.** A drop of blood is seen when the paper clip penetrates the nail plate and enters the hematoma. Place at least one additional hole in the nail plate to ensure drainage if the first hole becomes occluded.

The paper clip will not get as hot as a cautery device. More than one attempt may be necessary to penetrate a thick nail. This will generally require reheating of the paper clip. Another disadvantage of this technique is the possibility of introducing carbonaceous

FIGURE 127-6. The paper clip technique. The hot tip of the paper clip is centered over the subungual hematoma and allowed to penetrate the nail plate.

material into the hole. The use of an open flame may be potentially dangerous or prohibited in the Emergency Department.

DRILL TECHNIQUE

This technique uses a needle as a small drill to penetrate the nail plate (**Figure 127-7**). Small electric nail drills are available that greatly simplify this procedure, although they may not be readily available in the Emergency Department. Drilling through the nail plate may require a digital block. This is particularly true if there is a fracture, another associated injury, or the nail plate is very thick (i.e., toenails). Needles of various sizes can be used for this technique. There is typically a trade-off between the gauge of the needle and the bevel length. This can affect the ease with which the nail plate is penetrated. Most studies used an 18 gauge needle.

Grasp an 18 gauge needle by its hub with the dominant thumb and forefinger (**Figure 127-7A**). Place the tip of the needle over the nail plate and centered over the subungual hematoma. Spin the needle back and forth while applying gentle downward pressure. Small

FIGURE 127-7. Drill techniques. **A.** A twisting motion of the 18 gauge needle is used to penetrate the nail plate. **B.** A cotton-tipped applicator has been inserted into the hub of the needle. A twisting motion is used to penetrate the nail plate.

shavings will appear as the needle begins to drill through the nail plate. A loss of resistance will be felt as the hematoma is entered and darkened blood will flow from the hole. **Do not plunge as the nail bed can be injured in addition to causing additional pain.** Place at least one additional hole in the nail plate to ensure drainage if the first hole becomes occluded.

The editor uses a modified version of this technique (Reichman, personal communication). A cotton-tipped applicator may be wedged into the needle hub to facilitate the drilling (**Figure 127-7B**). This method makes the drilling more efficient. The cotton-tipped applicator is easier to hold and offers a mechanical advantage when it is twisted. The drill technique is very useful in the absence of a heat-generating device.

ALTERNATIVE TECHNIQUES

The PathFormer (Path Scientific, Carlisle, MA) is a U.S. Food and Drug Administration (FDA)-approved device for nail plate trephination (**Figure 127-8**).¹⁸ It allows for the precise control of the depth of penetration while making a 400 μ m diameter hole in the nail plate. The device is a battery-powered drill that automatically retracts the drill bit after the nail plate is penetrated. The sensitive and vascular nail bed is not contacted or injured. The electrical impedance triggers a feedback and the rapid retraction of the cutter when it penetrates the nail plate and enters the hematoma. The need for anesthesia is eliminated. The PathFormer device is not often available in Emergency Departments.

FIGURE 127-8. The PathFormer. **A.** The device. **B.** Three holes made in the nail plate with the device. (Courtesy of Path Scientific LLC, Carlisle, MA.)

Insulin needles can be used to drain a subungual hematoma.¹⁵ Insert the insulin needle underneath the nail plate and parallel to the hyponychium. Move the needle in a back-and-forth motion to evacuate the hematoma. This technique has been shown to cause little to no pain when compared with more traditional methods. It is limited to subungual hematomas that are near the free edge of the nail plate. This technique requires further studies of its safety and utility before it can be used in the Emergency Department.

Other devices have been used to drain a subungual hematoma. Battery-operated FDA-approved nail trephination devices are available for commercial use. Carbon dioxide lasers can be used to drain subungual hematomas. The laser beam is directed toward the center of the hematoma and results in quick and efficient drainage. The laser can be used without anesthesia because there is no contact with the nail bed itself.²⁴ These devices are not generally available in Emergency Departments.

ASSESSMENT

Squeeze the nail plate to evacuate the hematoma. Evaluate and manage any underlying injuries.

AFTERCARE

Inform the patient to keep the wound clean and monitor drainage. The nail plate may be covered with a nonadherent dressing. The hematoma may continue to drain for several hours or up to 1 to 2 days. The nail can be soaked in warm water and pressure applied to express the hematoma if there is a reaccumulation denoted by the reappearance of darkened blood beneath the nail plate. Inform the patient that the discoloration under the nail plate can persist for several weeks. Inform the patient that the nail plate may fall off and it can take up to 3 months for another nail plate to completely form. Apply a splint if a distal phalanx fracture is present. No studies have demonstrated that prophylactic antibiotics are beneficial in the management of a subungual hematoma.^{10,25-27} The patient should immediately return to the Emergency Department or their primary physician for fever, increased pain, purulent drainage from the nail, or any redness or swelling of the digit.

COMPLICATIONS

Direct complications from nail trephination are rare.^{12-14,17,20-22,25,28} Complications will more likely result from the original injury and include cosmetic deformities, infection, nail deformities, and nail loss.¹ Warn patients that loss of the nail is a possibility as the nail grows out. The rate of nail plate growth significantly slows for approximately 3 weeks after trauma before rapidly accelerating. This can cause a hypertrophic line to form along the nail plate.¹ Inform the patients that this is a possibility. Hypertrophic lines typically grow out with no residual cosmetic deformities. The hematoma may reaccumulate if the hole in the nail is too small and becomes occluded. Reaccumulation can be prevented by making a large hole or multiple holes in the nail plate. Plunging through the nail plate with a cautery unit or needle will cause the patient pain and injury to the nail bed that may be permanent and result in a deformed nail plate.

SUMMARY

Distal digit injuries are common. Patients will often present to the Emergency Department with a subungual hematoma and a complaint of pain. Rapid relief of pain, good cosmetic outcomes, and

good functional outcomes can be obtained in most cases by simply performing a nail trephination. It is important to distinguish when trephination alone will not be adequate therapy. Patients presenting with nail plate fractures, avulsions of the nail plate, or partial finger amputations will require removal of the nail plate and repair of the nail bed.

Subungual Foreign Body Removal

Ginger Clinton, Ameera Haamid, and Steven H. Bowman

INTRODUCTION

Subungual foreign bodies are often difficult to treat. Foreign bodies (e.g., hair, metal splinters, pencil lead, spines, thorns, and wood) may become lodged beneath the fingernail.¹⁻³ Tradesmen (e.g., auto mechanics, carpenters, landscapers, and metal workers) who work without hand protection with materials that produce small splinters are at risk for this type of injury. Subungual foreign bodies may present less commonly under the toenails.

Patients generally present for medical intervention with pain under the nail after unsuccessfully attempting to remove the foreign body. Prior removal attempts often result in breakage of the foreign body or pushing it further beneath the nail. This can complicate the next extraction attempt. Retained subungual foreign bodies if untreated can become infected, cause tissue reactions, and cause granuloma formation. Subungual foreign bodies can be treated rapidly with complete removal of the foreign body and without causing additional patient discomfort.⁴

ANATOMY AND PATHOPHYSIOLOGY

The distal fingertip and nail apparatus are complex structures (Figure 128-1). The perionychium is composed of the nail bed and the surrounding soft tissue. The hyponychium is the junction

FIGURE 128-1. The anatomy of the distal fingertip and nail bed. **A.** Surface anatomy. **B.** Midsagittal view.

FIGURE 128-2. Subungual foreign bodies can enter from under the distal nail plate or through the nail plate.

of the nail bed at the sterile matrix and the fingertip skin beneath the distal margin of the nail plate. The eponychium is the distal portion of the nail fold where it attaches to the proximal surface of the nail plate. The lunula is the white arc seen on the proximal portion of the nail plate. The nail bed consists of the germinal matrix on the proximal ventral floor of the nail fold and the sterile matrix that extends from the lunula to the hyponychium. The germinal matrix is primarily responsible for the growth of the nail. The subungual space is the area immediately beneath the nail plate.

Foreign bodies may enter the subungual space at the distal fingertip beneath the nail or may penetrate the nail plate (Figure 128-2). Separation of the nail from the nail bed results in severe pain. Patients frequently attempt to remove the foreign body immediately because of this intense discomfort. An infection or foreign body reaction will often ensue if the foreign body is not removed in its entirety.

INDICATIONS

Subungual foreign bodies should be removed to prevent the complications of foreign body reactions, infection, and possible nail deformity. Deeply embedded foreign bodies, splintered foreign bodies, those that traverse the nail plate, or contaminated foreign bodies may require the removal of the nail plate to extract the foreign body (Chapter 129). Consult a Hand Surgeon if the foreign body cannot be removed, if the site is infected, if the foreign body is “chronic,” if an osteomyelitis is present on radiographs, or if significant injury to the digit is present.

CONTRAINDICATIONS

There are no absolute contraindications to the removal of a subungual foreign body.

EQUIPMENT

GENERAL SUPPLIES

- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Sterile saline solution
- Topical antibiotic ointment
- Nonadherent dressing (e.g., petrolatum gauze)
- 4×4 gauze squares
- Adhesive tape

DIGITAL OR METACARPAL BLOCK

- 3 mL syringe
- 25 or 27 gauge needle, 1 inch long
- 3 to 5 mL local anesthetic solution without epinephrine

■ SCRAPE TECHNIQUE

- Splinter forceps
- #11 or #15 scalpel blade on a handle

■ WEDGE TECHNIQUE

- Splinter forceps
- Tissue scissors or nail clippers

■ NEEDLE TECHNIQUE

- Needles, 19 and 25 or 27 gauges
- Splinter forceps
- Hemostat

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Ascertain the patient's tetanus immune status and administer the appropriate tetanus prophylaxis if needed. Gain the patient's cooperation to make them more comfortable. Place the patient sitting or in a semi-recumbent position with their hand on a bedside procedure table.

Prep the finger. Clean any blood, dirt, or debris from the affected finger. Do this gently as any manipulation of the nail bed will result in additional patient discomfort. Apply povidone iodine or chlorhexidine solution and allow it to dry. Determine the need for a digital or metacarpal block based on the type of the foreign body, degree of embedment, and the chosen removal technique (Chapter 156).

Radiographs are not required unless a metallic foreign body cannot be visualized, the clinical suspicion exists for an osteomyelitis, or there is the suspicion for a gas forming finger infection. Ultrasound has been useful in visualizing the location and orientation of radiolucent foreign bodies.^{5,6} It has been described for confirmation of complete foreign body removal.^{5,6}

TECHNIQUES

The removal technique is chosen based on the location of the foreign body and Emergency Physician comfort. Foreign bodies protruding through or from underneath the nail plate can usually be grasped with forceps and removed whereas deeply located objects may require special techniques. A scalpel blade or 18 gauge needle may be used to entrap a small protruding tip of the foreign body against the nail plate and draw it out. **Do not attempt to remove the foreign body through a puncture wound or small incision.** Enlarging the access site allows for easier removal, not breaking or fragmenting the foreign body, and complete removal. Subungual foreign bodies may be removed by one of the following techniques.⁴

SCRAPE TECHNIQUE

This technique works well for foreign bodies that have traversed the nail plate, lodged beneath the distal nail, or lodged beneath the middle portion of the nail. This technique has been described anecdotally.^{7,8} It appears promising as it does not require the administration of a digital block and causes less trauma to the nail and the nail bed compared to other techniques.

Support the patient's hand on a procedure table. Sit on a chair facing the patient. Place a #11 or #15 scalpel blade on the nail plate directly over the foreign body (Figure 128-3A). Hold the blade perpendicular to the surface of the nail plate. Draw the scalpel blade

FIGURE 128-3. The scrape technique. **A.** Strokes are made in a proximal to distal direction with the scalpel blade held 90° to the nailbed. A U-shaped defect will be created to expose the foreign body. **B.** The foreign body is grasped and removed with forceps.

from proximal to distal using short strokes and gentle pressure over the foreign body (Figure 128-3A). A small shaving of the nail plate is removed with each stroke of the scalpel blade. Soak the finger in lukewarm water for 15 to 20 minutes to soften the nail plate if it is thick and difficult to shave. Continue to remove successive slivers of the nail plate to eventually create a U-shaped defect and expose the foreign body (Figure 128-3B). Grasp the foreign body with a splinter forceps and remove it once a significant portion protrudes (Figure 128-3B). The defect created in the nail plate will move distally and eventually be replaced as the nail plate continues to grow.

WEDGE TECHNIQUE

The wedge technique works well for subungual foreign bodies lodged beneath the distal portion of the nail plate.^{1,9} Patients will require a digital or metacarpal block prior to attempting this technique since it involves manipulation of the nail bed.

Sit on a chair facing the patient. Cut a triangular wedge from the distal portion of the nail plate overlying the foreign body with a small pair of tissue scissors or nail clippers (Figure 128-4A). **Prevent iatrogenic injury to the nail bed by ensuring that the tip of the scissors under the nail plate is aimed upward and against the nail plate.** Remove the wedge of nail. This will provide enough exposure to grasp and remove the foreign body with splinter forceps (Figure 128-4B).

NEEDLE TECHNIQUES

The needle technique works well for subungual foreign bodies located beneath the distal portion of the nail plate.¹ Patients will require a digital or metacarpal block prior to attempting this technique. Insertion of a needle into the nail bed is extremely painful. The major drawback of this technique is the potential for leaving fragments of the foreign body beneath the nail plate.

Sit in a chair facing the patient. Introduce a 19-gauge needle beneath the nail plate and along the track of the foreign body (Figure 128-5A).¹⁰ Use the tip of the needle to touch the foreign body. Lower the hub of the needle to raise its tip and trap the foreign body between it and the nail plate. Withdraw the needle

FIGURE 128-4. The wedge technique. **A.** A triangular incision is made in the nail plate overlying the foreign body. **B.** The cut section of the nail plate has been removed. The foreign body is grasped with forceps and removed.

while dragging the foreign body out along the nail plate. Alternatively, tease out and move the foreign body distally until it can be grasped with a splinter forceps.

Two alternate techniques have also been described for the needle extraction of a subungual foreign body.^{10,11} The first is a modification of the needle technique.⁷ Place a hook in the distal end of a 25 or 27 gauge needle with a hemostat or needle driver (**Figure 128-5B**). Pass the bent needle along the foreign body tract. Grasp the foreign body with the tip of the bent needle. Withdraw the needle to move the foreign body distally so that it may be grasped with a splinter forceps. The second technique involves the excision of a small portion of the nail plate overlying the foreign body with an 18 gauge needle.¹¹ This is similar to the shave technique with the exception of an 18 gauge needle being used instead of a scalpel blade.

FIGURE 128-5. Needle techniques. **A.** A 19 gauge needle is inserted along the tract of the foreign body. The tip is used to tease the foreign body out of the tissues. **B.** The tip of a 25 or 27 gauge needle has been formed into a hook. The needle is inserted along the tract of the foreign body. The tip is used to grasp the foreign body and pull it out of the tissues.

ASSESSMENT

Inspect the subungual area for any remaining fragments of the foreign body that may have broken off in the nail bed. Ultrasound may aid in this evaluation. **Any remaining fragments of the foreign body must be removed as to not cause complications as previously described.** Refer the patient to a Hand Surgeon if the foreign body fragments cannot be removed.

AFTERCARE

Local wound care and the application of a topical antibiotic ointment are all that is required in most cases. Irrigate the foreign body tract and excision site with sterile saline. Apply topical antibiotic ointment to the area. Apply a nonadherent dressing over the nail. Follow-up with a Hand Surgeon and systemic antibiotics may be necessary in severe cases (e.g., the presence of a nail deformity, chronic foreign bodies with an infection, or inability of the Emergency Medicine physician to remove the entire foreign body). Manage postprocedural pain with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). The use of prophylactic antibiotics is not recommended unless the foreign body was contaminated or deeply penetrated the soft tissue of the digit. Instruct the patient to return immediately to the Emergency Department if they develop any signs of an infection (i.e., fever, increased tenderness, purulent drainage, redness of the digit, or swelling of the digit).

COMPLICATIONS

There are a few potential complications from subungual foreign body removal. Damage to the nail bed can result in a residual nail deformity. Failure to completely remove a subungual foreign body may result in a nail deformity, abnormal nail growth, an infection, or a foreign body reaction with granuloma formation. An infection can result from a contaminated foreign body, flora on the nail plate, skin driven into the soft tissues by the foreign body, or if sterile technique is not followed.

SUMMARY

Patients with subungual foreign bodies often present with severe pain within the nail after prior unsuccessful attempts at removal or after complications develop. It is important that the Emergency Physician completely remove the foreign material in the subungual space to prevent further complications. Providing adequate anesthesia, using appropriate instruments, and using appropriate techniques allow the successful removal of most subungual foreign bodies.

Nail Bed Repair

Dayle Davenport

INTRODUCTION

The fingertip, the most sensitive area of the hand, is often our first contact with the environment. It has important functional roles in grasping and pinching, in addition to its sensory and cosmetic functions.^{1,2} The fingernail protects the fingertip and provides increased sensation to the volar pulp.³ However, it also conceals the true extent of fingertip injuries. Hand injuries, with the fingertips most frequently involved, are second only to back injuries as the most common occupational injuries resulting in loss of work days.⁴ Hence, it is important for the Emergency Physician to evaluate the full extent of the injury, to assess potential disabilities, and to recognize the need for prompt referral to a Hand Surgeon.

The fingernails are frequently injured due to their anatomic location and their functional role. **Immediate primary repair is the ideal management when these injuries involve the nail bed and surrounding skin fold structures.**^{3,5,6} Careful repair is necessary to avoid functional impairment and cosmetic derangement of the nail plate.⁷ The following discussion will refer primarily to the fingernail. The toenail has less importance, both cosmetically and functionally, as grasp and pinch are not needed. However, all the principles and recommendations made also apply to the toenail.⁸

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of the anatomy of the nail unit enables the Emergency Physician to recognize the types of injuries and provide anticipatory guidance of the consequences of these injuries to the patients. The “perionychium” or the nail unit consists of the nail fold, nail plate, nail bed, and hyponychium (**Figure 129-1**).^{1,2}

The nail plate enhances the sensibility of the fingertip by applying a counterforce to the pulp space nerve endings.³ The digital tip and the nail plate also function in unison to smoothly coordinate normal pinch and grasp which are important for picking up fine objects such as coins and pins.^{3,9}

The nail plate is comprised of compacted, flattened, and elongated anucleated cells that originate from cornified epithelial cells.¹⁰ There are three anatomic sites where these cells exist.^{5,9} The nail bed contains two of the sites: the sterile matrix and the germinal matrix (**Figure 129-1A**).^{1,9} The other location is the dorsal roof matrix. Of these, the germinal matrix is the most important for normal nail growth.⁵ The germinal matrix is responsible for approximately 90% of the nail plate by volume.⁹ The sterile matrix is responsible for a small percentage of the nail plate by volume and varies in each individual. This cell production accounts for the nail plate being thicker at its distal tip compared to its proximal origin.⁹ The nail cells from the dorsal roof matrix are small in number and form a very thin layer on the surface of the nail plate. These cells are responsible for the shine of the nail. The nail will lose its shine and become dull if the dorsal roof matrix cells are destroyed.

Skin overlies the nail plate proximally and laterally (**Figure 129-1B**).¹⁰ The proximal skin fold is referred to as the eponychium.

FIGURE 129-1. Anatomy of the fingernail. **A.** Lateral view. **B.** Top view. The colored area represents the perionychium.

The eponychium protects the germinal matrix located in the proximal nail bed and is the home of the dorsal roof matrix. The skin immediately over the dorsal roof is called the nail wall.⁹ The lateral skin folds, the adjacent cutaneous areas, and the adjacent nail bed (i.e., germinal matrix and sterile matrix) are collectively referred to as the perionychium (**Figure 129-1B**).^{7,9,10} The lunula is the pale arc just distal to the eponychium and roughly corresponds to the location of the germinal matrix.^{1,2,9,10}

The nail bed is composed of the germinal matrix proximally and the sterile matrix distally, with the junction of these two at the level of the lunula.^{1,9} The borders of the nail bed are the proximal nail fold, the lateral nail folds, and the hyponychium distally. The hyponychium is the thick layer of cells at the junction of the distal nail bed (i.e., the sterile matrix) and the fingertip skin.⁹ It is located just under the distal free margin of the nail plate (**Figure 129-1A**). The hyponychium serves as a barrier preventing the delicate nail bed from exposure to bacteria and fungi.⁹

The rate of nail growth varies from finger to finger, from individual to individual, and varies with age.^{3,9} Nail growth is fastest between 4 and 30 years of age and after 80 years of age. Fingernails grow four times faster than the toenails.¹ A new nail takes a minimum of 4 months to grow and even longer following an injury. Progression of the distal nail occurs at a rate of 0.1 mm/day or 0.5 to 1 mm/week.^{3,10} This rate varies and is usually faster in fingers than

in toes and faster in the summer months.³ The pressure of new cells being formed leads to the flattening and elongation of the older cells as well as their progression distally.⁹

The sterile matrix is more adherent to the nail plate than to the adjacent germinal matrix. Therefore, avulsions involving nail bed tissue are more likely to occur at the sterile matrix.^{9,11,12} Conversely, the nail plate is loosely held to the germinal matrix. This accounts for the peculiar injury of avulsions of the proximal nail plate from the proximal nail fold while the distal nail plate remains attached (Figure 129-2).

The digital artery supplies the volar radial and ulnar sides of the finger. It consistently sends even smaller branches to the proximal nail fold and to the nail bed, producing a rich capillary network.¹ The small veins of the nail bed, pulp, and lateral nail folds coalesce proximally to form a larger commissural vein that runs lateral to the distal phalanx and a terminal vein that runs dorsal to the distal phalanx. The digital nerve accompanies the digital artery and sends branches beyond the distal interphalangeal joint and into the nail fold, nail bed, and finger pulp. The extensor tendon attaches itself to the distal phalanx just proximal to the germinal matrix.^{9,12} The periosteum of the distal phalanx, in turn, closely adheres to the sterile matrix.⁹

Certain patterns emerge as a result of an injury. Avulsions of the nail bed tend to occur in the sterile matrix rather than the less adherent germinal matrix. Another pattern of injury seen is the avulsion of the proximal nail plate from the proximal nail fold while the distal part remains attached to the nail bed (Figure 129-2). Because the sterile matrix closely adheres to the periosteum of the distal phalanx, fractures of the distal phalanx might injure the nail bed, producing a subungual hematoma.⁷ Due to the close proximity of the germinal matrix and the attachment of the extensor tendon, injuries to or repair of these structures might involve the other. A subungual hematoma is a collection of blood between the nail bed and the nail plate. Although controversial, a large subungual hematoma may require repair of the underlying nail bed.

FIGURE 129-2. A crush injury to the distal fingertip. **A.** Proximal nail bed avulsion. **B.** A more severe crush injury can result in a proximal nail bed avulsion and fracture of the distal phalanx. Note that the distal nail plate remains attached to the sterile matrix in both of these injuries.

Emergency Physicians must consider in each case whether there exists enough damage to require surgical nail bed repair. It is important to note that significant force is required to break, penetrate, or avulse the nail plate.⁷ Therefore, the fragile nail bed is most likely disrupted if the nail plate is disrupted.

INDICATIONS

Injuries to the fingertip and nail, if not initially managed correctly, have long-lasting functional and cosmetic consequences. The most important consideration is functional.¹⁰ Normal nail growth after an injury requires a smooth nail bed. Therefore, nail bed injuries must be meticulously repaired to prevent cosmetic deformities and functional impairment.¹⁰⁻¹² Scar tissue may form between the wound edges if the nail bed is not accurately approximated. This scar tissue will not form the intermediate nail cells responsible for nail adherence.⁹ Loss of the germinal matrix alone will result in permanent loss of the nail plate.^{5,13} **The skin folds surrounding the nail margins must also be preserved.**^{5,12} Failure to do so will result in the painful complication of adhesion formation between the skin fold and the nail bed.^{5,12} Secondary repair of these spaces, or of the nail bed, requires more complex procedures and is usually associated with a poor outcome.^{4,11} **Therefore, every effort should be made to primarily repair all significant nail bed injuries.**

CONTRAINDICATIONS

No absolute contraindications exist for primary nail bed repair. Any life-threatening injuries, limb-threatening injuries, and/or uncontrolled hemorrhage must be addressed prior to nail bed repair.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Restraining device, as necessary
- 10 mL syringe armed with a 27 gauge needle
- Local anesthetic solution without epinephrine (1% lidocaine or 0.25% bupivacaine)
- Digital tourniquet
- #15 scalpel blade on a handle
- Magnification device
- Sterile prefabricated nail, if available
- Nonadherent petrolatum gauze
- 5-0, 6-0, and 7-0 chromic gut (or polyglactin 910 or irradiated polyglactin 910) on a P-3 cutting needle
- 6-0 monofilament nylon sutures
- 2-Octylcyanoacrylate (e.g., Dermabond) or another tissue adhesive
- Needle driver
- Curved hemostat
- Fine scissors or periosteal elevator
- Forceps
- Sterile towels or drapes
- Sterile gloves
- Dry gauze or tube gauze
- Splinting material
- Battery-powered electrocautery device

The use of a digital tourniquet is essential to properly repair a nail bed. Its use provides a bloodless field. This allows for a more meticulous and precise wound approximation. Complications associated

FIGURE 129-3. A sterile Penrose drain or IV tourniquet used as a digital tourniquet.

with their use includes neurovascular injury secondary to excessive tourniquet pressure and digital ischemia caused by a forgotten tourniquet. Numerous options are available to use as a tourniquet in the Emergency Department. These include the use of a sterile Penrose drain, rubber intravenous (IV) tourniquet, or sterile glove. A sterile Penrose drain or IV tourniquet secured with a hemostat is often used as these items are readily available (**Figure 129-3**). A sterile glove may be used as a tourniquet (**Figure 129-4**). Apply a sterile glove onto the patient's hand that is snug or a size one-half smaller than their actual glove size. Cut just the tip off the glove over the affected finger(s). Roll the cut finger back and onto the proximal phalanx to form the tourniquet (**Figure 129-4**).

Several commercially produced digital tourniquets are often available in the Emergency Department. The Tourni-cot (Mar Med Co., Grand Rapids, MI) is a sterile, single-use, disposable, rubber ring that slides over the fingertip and is rolled backward until it rests over the proximal phalanx (**Figure 129-5**). These come in several sizes to fit the appropriate finger size. The advantage of the Tourni-cot is that it exsanguinates the digit as it is applied. The T-Ring (Precision Medical Devices LLC, San Clemente, CA) is a "one size fits all" digital tourniquet (**Figure 129-6**). It is a sterile, single-use, disposable, rubber diaphragm with a central hole. It slides over the fingertip and is pushed backward until it rests over the proximal phalanx.

FIGURE 129-4. A sterile glove used as a digital tourniquet.

FIGURE 129-5. The Tourni-cot digital tourniquet.

The T-Ring also exsanguinates the digit as it is applied. The Tourni-cot and T-ring are superior to the glove and Penrose drain in providing hemostasis with the least amount of pressure.¹⁴

PATIENT PREPARATION

The first step in the evaluation of fingertip injuries is obtaining a thorough history.¹⁵ The mechanism of injury can provide some clues to the type and extent of injuries as well as amount of contamination to be expected. Other pertinent information includes the patient's age, hand dominance, occupation, hobbies, comorbidities, and tetanus vaccination status. All significant injuries to the fingertip should be evaluated radiographically for fractures. The management of fingertip injuries may differ in the presence of a fracture. Thoroughly evaluate and document a complete neurovascular examination, tendon function and intactness, and ligamentous stability of the joints. Administer tetanus immune prophylaxis if required.

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. **It is important to explain both the risks of doing the procedure and of not doing the procedure.** Document this conversation and obtain an informed consent. Place the patient on a gurney with the hand on a bedside procedure table in a well-lit area. Be prepared to use age-appropriate

FIGURE 129-6. The T-Ring digital tourniquet.

sedation or to apply appropriate restraints for children.¹² Procedural sedation may be necessary in patients who are agitated, uncooperative, or require extensive repair. Apply a type of magnification device if available. This may consist of a head-strap device, a swing arm device, magnification glasses, or loupe magnification glasses.

Anesthetize the injured digit(s) involved (Chapter 156). Anesthesia may be achieved with a digital block or a metacarpal block when only a single digit is involved.^{7,15} Lidocaine (1% or 2%) can provide pain relief of up to 3 hours. For longer analgesia, use 0.5% bupivacaine or lidocaine with epinephrine, with multiple studies showing that the risk of digital necrosis is minimal.¹⁶⁻¹⁹ Metacarpal blocks or an axillary nerve block may be performed if multiple digits are involved.⁷

Thoroughly clean the hand of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry.²⁰ Irrigate the wound with sterile saline. If the nail plate has been avulsed, irrigate it with a dilute povidone iodine or chlorhexidine solution followed by a gentle rinse with sterile saline. **It is important not to scrub the undersurface of the avulsed nail plate because adherent squamous tissue may be destroyed.**⁷

A bloodless field is desired and, in many cases, necessary. Apply a digital tourniquet as described in the equipment section above.⁷ If available, a pneumatic tourniquet may be placed on the arm instead of using the digital tourniquet. The pneumatic tourniquet is especially helpful when the patient has fractures or lacerations of the proximal digit that preclude the use of a digital tourniquet. **Avoid using a blood pressure cuff as these tend to deflate during use. As with all tourniquets, limit the amount of time in which the tourniquet is in place.** Create a sterile field by applying sterile towels.

TECHNIQUES

Adhering to certain principles will improve the outcome when repairing nail beds. A smooth and flat nail bed is necessary to the normal growth of the nail and should be the primary goal in any repair. Avoid or severely limit the amount of debridement.⁵ The germinal matrix must be meticulously repaired and the proximal nail fold (i.e., the eponychium) preserved or that space is obliterated within a few days and can result in adhesions or abnormal nail growth.⁵ Thoroughly clean and replace the nail plate whenever possible. This will preserve the nail folds surrounding the nail bed, allow the nail plate to serve as a splint for fractures, and act as a protective cover for the healing nail bed.⁷ Treatment goals also include preservation of length and sensation of the fingertip, early mobilization, prevention of joint contractures, and attention to cosmesis.^{4,21}

The technique of nail bed repair depends on the type of injury as well as which structures are involved. Various classification schemes, such as the nature of injury or anatomic location, have been developed to categorize fingertip injuries and guide treatment. Nail bed injuries are classified as simple lacerations, crushing lacerations, avulsion-lacerations, lacerations with associated fractures, lacerations with loss of skin and pulp, and fingertip amputations.^{2,12}

NAIL PLATE REMOVAL

A significant force is required to break the nail plate. **The nail plate should be removed to visualize the underlying nail bed if the nail plate is damaged or avulsed or if the lateral skin folds are lacerated, as this makes an associated nail bed injury highly likely.** Removal of the nail plate is unnecessary in minor injuries where the nail plate is not damaged and still attached to the nail folds.

Remove the nail plate to repair nail bed injuries or to inspect the nail bed for potential injuries (Figure 129-7). Insert the closed tips of a fine scissors between the nail bed and the nail plate. A periosteal

FIGURE 129-7. Removal of the nail plate. Dissect along the plane between the nail plate and the nail bed using a pair of fine scissors or periosteal elevator.

elevator, if available, can be substituted for the scissors. Hold the scissors parallel to the long axis of the finger. Slightly angle the tips of the scissors toward the nail plate to prevent any damage to the nail bed.¹² Advance the tips of the scissors in 1 to 2 mm increments. Open the blades of the scissors to separate the nail bed from the nail plate. Close the blades of the scissors. Continue to advance the tips of the scissors in 1 to 2 mm increments and separate the nail bed from the nail plate. Stop advancing the scissors when the tips of the blades are at the level of the eponychium. Firmly grasp the nail plate with a hemostat. Pull the nail plate parallel to the long axis of the finger to completely remove it from the finger.

Making two linear incisions with a scalpel at 90° from the eponychium edge will allow for greater exposure to the germinal matrix for the repair (Figure 129-8).⁸ This allows the eponychium to be folded or sutured back and therefore increases the exposure of the germinal matrix.^{2,21}

SIMPLE LACERATIONS

Simple lacerations are caused by localized blows to the nail plate. After removing the nail plate and exposing the nail bed, repair the laceration meticulously using 6-0 or 7-0 chromic gut or irradiated polyglactin 910 sutures.^{2,7,21} Alternatively, 2-ethylcyanoacrylate (e.g., Dermabond) can be used and has no difference in cosmesis, pain, or functional ability and was significantly faster than suturing.^{22,23}

Minimize debridement as much as possible to avoid scarring that

FIGURE 129-8. Incisions can be made at 90° to the corners of the eponychium for better exposure of the germinal matrix.

FIGURE 129-9. Crushing lacerations to the nail bed. **A.** Stellate or complex lacerations of the nail bed can occur after a crush injury. **B.** Approximation of the nail bed with fine absorbable sutures.

will result in nonadherence or splitting of the nail plate. Repair any skin lacerations adjacent to the nail bed using 6-0 or 5-0 monofilament nylon sutures.⁵ Nail fold lacerations may require repair in layers in order to preserve these spaces.¹⁰

CRUSHING LACERATIONS

The second type of injury is a crush injury with resultant lacerations. Crushing injuries may produce stellate lacerations and fragmentation of the nail bed (**Figure 129-9A**). Attempt to meticulously repair the fragmented nail bed using 6-0 or 7-0 chromic gut, irradiated polyglactin 910 sutures, or tissue adhesive to achieve precise approximation and the smoothest result possible (**Figure 129-9B**).^{7,22,23}

AVULSION-LACERATIONS

The third type of nail bed injury is the avulsion-laceration (**Figure 129-10A**). These injuries are more complex and sometimes the fingernail is too damaged to be repositioned. In these cases, a nail substitute should be used to protect the fingernail during the healing process and to avoid adherences along the proximal nail bed and nail fold.²⁴ Distal nail bed avulsions simply require petrolatum gauze to be placed over the injury followed by sterile gauze. Suture the petrolatum gauze and sterile gauze in place using 5-0 or 6-0 nylon suture for 10 days to allow the wound to heal by second intention (**Figure 129-10B**).^{5,21} Avulsion-laceration injuries may require consultation with a Hand Surgeon depending on the amount of tissue involved and whether the germinal matrix is involved.^{7,12,13} More severely damaged nail beds with a large amount of avulsed tissue usually require dermal grafts or split-thickness matrix grafts.⁷

Small fragments of avulsed nail bed may remain attached to the nail plate. If only the sterile matrix is damaged, the nail should be left attached proximally in the nail fold.²⁵ These may be simply treated by carefully replacing the nail plate in its anatomic position. Larger segments of avulsed nail bed that remain attached to the nail plate should be repaired (**Figures 129-11A and 129-11B**). Gently shave away the nail bed from the nail plate with a #15 scalpel blade (**Figure 129-11C**). Replace the avulsed nail bed and suture it in place with 5-0 or 6-0 chromic gut, irradiated polyglactin 910 sutures, or tissue adhesive (**Figure 129-11D**).^{11,22,23} Apply a petrolatum gauze dressing and replace the nail plate.

A special type of avulsion injury occurs when there is a crush injury to the distal fingernail. This results in an avulsion of the proximal nail plate with or without involvement of the germinal matrix (**Figure 129-2**). The proximal nail plate is less adherent to the nail bed and can be pulled out from under the eponychium (**Figure 129-2**). Remove the nail plate if the proximal nail plate is avulsed without

FIGURE 129-10. Avulsion-laceration of the nail bed. **A.** The dorsal aspect of the fingertip is avulsed with the nail plate. **B.** Petrolatum gauze is placed over the injury. This is subsequently covered with sterile gauze and sutured into place for 10 days.

FIGURE 129-11. Large avulsion of the nail bed that is adherent to the nail plate. **A.** Lateral view of injury. **B.** Top view of injury. **C.** Gently shave away the avulsed segment. **D.** Repair the nail bed using the avulsed segment.

involvement of the germinal matrix. Clean the nail plate and nail bed with sterile saline. Replace and secure the nail plate.

More often with these crush injuries, the germinal matrix is avulsed as well. In these cases, the germinal matrix should be replaced with a series, usually three, of 6-0 nylon simple interrupted or horizontal mattress sutures (**Figure 129-12**).^{5,7,11} Place all three sutures before returning the nail bed to its proper location. Making two linear incisions with a scalpel at 90° from the eponychial edge will allow exposure to the germinal matrix for repair (**Figure 129-8**).⁸ This allows the eponychium to be folded or sutured back and therefore increases the exposure of the germinal matrix.^{2,21} Place a piece of petrolatum gauze between the eponychium and the germinal matrix after the repair (**Figure 129-12B**). Larger germinal matrix avulsions require consultation with a Hand Surgeon for grafting.^{2,7,12,20}

LACERATIONS WITH ASSOCIATED FRACTURES

The fourth type of nail bed injury are lacerations associated with fracture(s). Approximately 50% of nail bed injuries have an associated phalangeal tuft fracture.²⁴ The nail bed laceration should be repaired as previously described and the fracture addressed as a separate entity.⁵ It is important to remember that the sterile matrix is closely adherent to the dorsal periosteum of the distal phalanx. Therefore, fractures require precise anatomic reduction in order for normal nail bed healing and nail plate growth to take place.^{7,11,13} Replacing the nail plate and splinting the finger after repairing the nail bed laceration is often enough to reduce these fractures. Occasionally, fixation may be employed by a Hand Surgeon using Kirschner wires to prevent rotation of the bony fragments.^{2,7,24}

LACERATIONS WITH SKIN LOSS AND FINGERTIP AMPUTATIONS

The final two types of injury are lacerations with loss of skin and pulp and fingertip amputations.²⁶ They can be further classified according to zones based upon the anatomic level of amputation (**Figure 129-13**).³ Zone I injuries occur distal to the bony phalanx. These do not result in loss of function and rarely result in a cosmetic deformity. Management consists of cleansing, placing topical antibiotic ointment over the injured area, and then applying a layer of petrolatum gauze. This should be followed by a sterile dressing and a splint. Zone II injuries occur distal to the lunula and over the bony phalanx. These injuries often have exposed bone. Zone III injuries occur proximal to the distal end of the lunula. Zone II and zone III

FIGURE 129-13. Classification of fingertip injuries. Zone I is distal to the bony phalanx. Zone II is distal to the lunula and over the bony phalanx. Zone III is proximal to the distal end of the lunula.

injuries should be managed in consultation with a Hand Surgeon. Either type of injury may require reconstruction with a pedicle flap and/or skin grafting.³

TREPHINATION FOR A SUBUNGUAL HEMATOMA

A subungual hematoma is a collection of blood under the nail plate caused by blunt trauma to the fingertip. The nail bed is usually crushed or lacerated with resultant extravasation of blood into the plane between the nail plate and the nail bed.¹² Compression of nail bed nerves occurs and often causes significant pain as pressure builds up. Usually this pain is what causes the patient to seek medical attention. The management of subungual hematomas (Chapter 127) is discussed separately because these injuries are typically minor and treated by simple trephination.²⁷

It is generally accepted that subungual hematomas less than 50% of the nail plate may be managed conservatively by simple trephination (i.e., puncture) of the nail plate.^{2,5,7,12,21,28,29} This allows for drainage of blood and immediate pain relief. No anesthesia is usually necessary for this procedure. This is accomplished with the use of an electrocautery device creating a 3 to 4 mm hole in the nail plate overlying the hematoma. The nail plate should be clean and dry for this procedure. A heated paperclip may be used if an electrocautery device is not available.⁵

Some controversy exists over the management of subungual hematomas greater than 50% of the nail plate.³⁰ The concern is that a larger hematoma may hide an occult laceration that requires repair in order to avoid the complication of step-off with subsequent ridging as the new nail grows back. Some authors feel that it is impossible to accurately assess the amount of damage beneath a subungual hematoma unless the nail plate is removed to directly inspect the nail bed.^{7,29} These authors noted that subungual hematomas that have separated greater than 50% usually have lacerations that require repair. Another study found that a subungual hematoma with more than 50% separation had a 60% incidence of having a nail bed laceration that required repair and up to a 95% incidence when there was an associated phalanx fracture.²⁹ In contrast to these studies, a prospective study found no complications at 6 months of follow-up for subungual hematomas treated by electrocautery trephination alone.^{2,28} This was regardless of the size of the subungual hematoma or the presence of a fracture. These authors feel that removing the nail plate and attempting repair may actually cause further trauma to the nail bed.²⁸ These results were also duplicated in the pediatric population, with trephination alone having results that were equal to or better than removal of the nail.³¹ Nail removal and primary care of the laceration are recommended in the case of disruption of the nail plate or nail fold or with displaced fracture fragments.³²

It was previously recommended that radiographs be obtained to rule out a fracture for all hematomas larger than 50% of the nail plate. A newer study found no correlation between the size of the hematoma and the presence of fractures.²⁸ **Have a low threshold**

FIGURE 129-14. A hole is placed in the nail plate before it is sutured in place.

to obtain plain radiographs prior to evacuating the hematoma if a fracture is suspected. This is especially important in children, where proper bony alignment and stability are necessary for normal finger growth.³² Bedside ultrasound is a promising tool for detecting nail bed injuries and tuft fractures.^{33,34}

In summary, most subungual hematomas may be treated by simple nail trephination using an electrocautery device. This procedure will lead to beneficial drainage only if done before 36 to 48 hours from the time of the injury.¹² The clinical benefit of nail bed repair with larger subungual hematomas is controversial but may not be necessary if the nail plate is adherent to the nail bed and is without laceration. Nail plate removal and nail bed repair are favored in cases where a proximal fracture involves the germinal matrix, a displaced fracture of the distal phalanx, or laceration with injury to the nail plate.³⁵ It may be prudent to maintain a lower threshold for nail bed repair with a larger subungual hematoma, particularly if an ideal cosmetic outcome is desired.

AFTERCARE

Whenever possible, the nail plate should be replaced after repairing any of the previously mentioned injuries. The nail plate covers the sensitive nail bed and protects it from injury, maintains the proximal nail fold (i.e., eponychium) to allow for growth of a new nail, and splints the nail bed. Place a hole in the center of the nail plate to allow for fluid drainage to accomplish the best outcome.¹² Make one or two holes in the lateral aspects of the nail plate. Suture the nail plate in place using 5-0 nylon sutures through the lateral skin folds (Figure 129-14).^{7,11,12} A figure-of-eight suture technique to attach the nail does not require an intact eponychial fold and minimizes iatrogenic trauma (Figure 129-15).³⁶ Place an absorbable suture (4-0 in adult, 5-0 in children) into one side of the paronychia in a distal to proximal fashion. Run the suture through the notches in the distal aspect of the nail plate and then place them from distal to proximal in the opposite paronychia. The suture

FIGURE 129-15. Figure-of-eight suture for securing the nail plate.

is then tied across the nail plate to create a figure-of-eight pattern (Figure 129-15). Remove these sutures securing the nail plate after 3 weeks, at which time the nail will be adherent or slough to allow for new nail growth.³⁷ An alternative to suturing the nail plate in position is to use tissue adhesive. Replace the nail plate and apply tissue adhesive along the eponychium and lateral nail folds where they overlap the nail plate.

A nail alternative should be used if the patient's nail is not available, too fragmented, or too dirty to use as a natural splint. Numerous materials have been suggested for nail bed covers, including the reservoir of an infusion set, acrylic nails, a nasogastric catheter splint, and the aluminum suture package material.^{24,37-39} An artificial nail may be used if the original nail plate is not available. The potential problem with sterile prefabricated nails is that there exists an increased risk for infection and a risk of erosion into the nail bed or nail folds.⁷ The editor recommends petrolatum gauze be used to maintain the nail fold structures when the original nail plate is not available or significantly damaged (Figure 129-16).

After repair of the nail bed, the digit(s) involved will need to be bandaged in order to protect it from infection, moisture, and trauma. The application of becaplermin (i.e., recombinant human platelet-derived growth factor) has been shown to improve outcomes.⁴⁰ This substance is not routinely used in the Emergency Department and should be applied after consultation with a Hand Surgeon. Place petrolatum gauze over the nail bed to avoid adherence from secretions. Apply a tube gauze dressing followed by a digital aluminum splint.³ Movement of the distal interphalangeal joint should be restricted for 7 to 10 days with a splint.⁷ The entire hand should be dressed for infants and young children. Remove any petrolatum gauze used to keep the proximal nail fold (i.e., eponychium) open in 5 to 10 days.⁷ Petrolatum gauze used to keep open the lateral nail folds (i.e., perionychium) should remain in place for 10 days.⁵ Any sutures placed in the skin structures or nail folds should be removed in 7 to 10 days.⁵

Prophylactic antibiotics are not routinely required. They are recommended for large avulsions, amputations, animal or human

FIGURE 129-16. Petrolatum gauze may be placed between the dorsal roof and germinal matrix (A) or between the lateral skin fold and nail bed (B) to preserve the skin fold spaces.

bites, and associated fractures when there is contamination with organic material.⁷ Topical antibiotics may be applied to zone I fingertip amputations. All injuries require a wound check in 24 to 72 hours.^{3,5,7} The patient's tetanus immunization status should be determined and prophylaxis administered if required. The hand should be elevated whenever possible. Nonsteroidal anti-inflammatory drugs supplemented with 1 or 2 days of narcotic analgesics may be prescribed as needed for pain control.

It is important to explain to the patient that regeneration of a new nail may take up to 6 to 12 months.⁷ Warn the patient that the new nail may look irregular and snag on cloth or string objects.⁷ The patient should trim and file the leading edge of the new nail once it extends past the hyponychium in order to avoid snagging.

COMPLICATIONS

The complications associated with failure to repair or improper repair of a nail bed can be functional, cosmetic, or both. The more serious complications are those that impair function or cause pain. There are basically seven complications that may arise. These exclude the infectious complications (e.g., abscess formation, cellulitis, and lymphangitis) that are inherent to all wounds. The occurrence of osteomyelitis from these injuries is rare, even with open fractures.²⁵ The seven complications are loss of the nail, a split nail, a nonadherent nail, an ingrown nail, a malaligned nail, wide nails, and narrow nails.¹³

The complete loss of a nail could result in significant functional impairment to the fingertip as well as an abnormal-looking fingertip. Complete nail loss occurs when there is complete disruption of the germinal matrix, either by significant avulsion of the matrix or amputation. Remember that if the germinal or roof matrices are not repaired, the pouch deep to the proximal skin fold (i.e., eponychium) is obliterated within a few days.²⁸

A split nail occurs when the germinal matrix is improperly approximated.^{5,7,13,24} A wide scar will result that will not form a new nail. Subsequently, a split nail develops. This can be avoided by the careful approximation of the nail bed with sutures.

A nonadherent nail occurs when the nail bed is not repaired and granulation tissue forms secondarily. The nail plate will not adhere at the site of the granulation tissue as well as distal to the granulation tissue.¹³ The nail can snag and be exposed to repeated tears once the nail plate loses adhesion to the nail bed.

The nail plate may ingrow if the lateral skin folds or sulci are not maintained and kept open.¹³ Adhesions that form between the skin and nail bed can be very painful when the new nail tries to grow through that space.⁵ Ingrown nails also have the long-term problem of a higher rate of infections (e.g., a paronychia). This can be avoided by the replacement of the nail plate or the placement of petrolatum gauze to elevate the lateral nail fold from the nail bed.

The nail plate will grow in a malaligned direction if the matrix is displaced or repaired in such a manner that it is improperly aligned.¹³ Functional impairment and cosmetic deformity may ensue depending upon the degree of this misdirected growth.

Wide nails often result from a crush injury with a tuft fracture.¹³ Separated bony fragments leave the nail bed flatter and wider. Narrow nails occur when a central avulsion-laceration is not repaired. Scar tissue forms in the center and allows the intact lateral portions to contract toward each other.¹³ The new nail subsequently becomes narrow and thick.

Tubular gauze dressings are commonly applied after the repair of a nail bed. **Tubular gauze dressings can result in significant injury when improperly placed.**^{25,41} This includes digital ischemia that may be permanent and require an amputation. **Tubular gauze dressings should not be placed by personnel not trained in their proper application.**

SUMMARY

Nail bed injuries are common and may result in a cosmetically deformed or functionally impaired fingertip. Complications may occur even with precise repair. The treatment of choice is immediate primary repair of the nail bed and surrounding structures. Remember to minimize any debridement and to replace the nail plate whenever possible. Injuries with associated fractures and simple subungual hematomas are managed separately from the nail bed injury. Always be thorough and meticulous when repairing nail bed injuries to provide the best possible outcome. Finally, know when to consult with a Hand Surgeon.

Ganglion Cyst Aspiration and Injection

Thomas P. Graham

INTRODUCTION

Ganglion cysts (i.e., synovial cysts or ganglia) are the most common soft tissue tumors of the wrist and hand.¹ They are a common reason for patients to present to the Emergency Department. The chief complaint is usually a mild pain or ache, exacerbated by movement, and localized to a 1 to 2 cm mass on the wrist or hand (**Figures 130-1, 130-2, and 130-3**). Patients may also present with concerns about a painless "lump." Acute trauma prior to presentation is uncommon. Patients often give a history of repetitive motion at the site. The mass usually increases in size progressively over time or occasionally may grow rapidly over a short period. Patients presenting to the Emergency Department with ganglia may have already attempted one of several popular home remedies (e.g., homeopathic medications or striking the cyst firmly with a large book or hammer).

Ganglion cyst aspiration is a relatively simple procedure that may be performed by the Emergency Physician. The practice of cyst aspiration has been challenged because of the high recurrence rates of up to and even greater than 50%.²⁻⁶ The procedure usually alleviates presenting symptoms, is occasionally curative, and is more cost-effective than referring all patients for surgical treatment.⁷

ANATOMY AND PATHOPHYSIOLOGY

Ganglia are synovial cysts that originate from a joint capsule or tendon sheath.⁸ They have no malignant potential. It is unclear whether ganglia are formed by herniation of the tendon sheath, myxomatous

FIGURE 130-1. Oblique view of the wrist demonstrating a ganglion cyst overlying the scapholunate joint. (Used from James Heilman, MD at www.commonswikimedia.org.)

degeneration of connective tissue, or some other mechanism. Contained within the cyst is a viscous, jelly-like fluid. Ganglia often connect with the underlying synovial cavity or tendon sheath by a stalk (**Figure 130-2**). Hyaluronic acid makes up all or part of the mucoid fluid.⁹

Ganglia are usually encountered on the dorsum of the wrist, in particular over the scapholunate ligament (**Figures 130-1, 130-2, and 130-3**). They may also be found on the palmar surface of the wrist, the lateral surface of the wrist, or on the hand itself. Ganglia of the foot and ankle are less commonly seen.¹⁰ Ganglia are less commonly encountered in other areas (e.g., shoulder, hip, elbow, knee, lumbar spine, temporomandibular joint, and the odontoid process of the cervical spine).¹¹⁻¹³

Ganglia present as fixed or slightly movable masses that are usually solitary. The cyst is frequently characterized as smooth and "rubbery." Cysts may become more noticeable with wrist flexion. They vary in size from barely palpable to 3 cm in diameter, with smaller than 1.5 cm being the norm. Tenderness is sometimes but not invariably present. Ganglion cysts will transilluminate since they are fluid-filled. They may "disappear" over time by spontaneously rupturing or due to resorption.

Diagnosing a ganglion cyst is usually not difficult. Ganglia of the foot and other uncommon locations may be difficult to palpate despite causing significant discomfort. The differential diagnosis of ganglia includes epidermoid cysts, xanthomas, rheumatoid nodules,

FIGURE 130-2. Cross-section through the scapholunate joint demonstrating a ganglion cyst. The needle is inserted into the cyst cavity to aspirate its contents.

benign tumors (e.g., lipomas and neuromas), joint capsulitis, and other soft tissue neoplasms (e.g., sarcomas and chondrosarcomas). Ultrasonography can be used to aid in the diagnosis, particularly of occult ganglia or ganglia presenting atypically.¹⁴⁻¹⁶ Magnetic resonance imaging (MRI) is frequently used to confirm the diagnosis and plan its operative removal.^{15,17,18} Plain radiographs and laboratory tests are not helpful in the work-up of a ganglion cyst.

INDICATIONS

The most common indication for ganglion aspiration is worsening pain and swelling, in particular when normal range of motion is restricted or occupational disability is present. Failure of conservative measures (e.g., rest, splinting, and the use of nonsteroidal anti-inflammatory drugs) to resolve symptoms may prompt ganglion aspiration in the Emergency Department.

CONTRAINDICATIONS

There are few contraindications to ganglion cyst aspiration. Avoid introducing a needle through an area of cellulitis. Cellulitis overlying a ganglion is uncommon and should raise suspicion for an alternate diagnosis (e.g., a skin abscess). The procedure can be safely deferred and the patient referred to a Hand Surgeon if the diagnosis of a ganglion is uncertain.

The location of a ganglion is generally not a contraindication to aspiration. Defer the procedure if there is a concern that the aspirating needle could damage an adjacent structure, cause neurologic injury, or cause vascular injury. Aspiration of palpable lower extremity ganglia may be performed in a similar fashion to hand and wrist lesions with similar results.^{10,19} Some literature suggests that volar wrist ganglion cysts recur at an even higher rate than those of the dorsal wrist and lower extremity. This has led some authors to recommend surgical excision as the primary therapy for this subset of ganglia.²⁰

EQUIPMENT

- Sterile gloves
- Povidone iodine solution or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 25 or 27 gauge needle on a 3 mL syringe for local anesthesia
- 16 or 18 gauge needle on a 5 or 10 mL syringe for aspiration
- 10 to 15 mg methylprednisolone acetate (20 mg/mL) or prednisolone tebutate (20 mg/mL)

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Obtain an informed consent, either signed or verbal, with adequate documentation to support the latter method. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Ultrasonography can be used to confirm the diagnosis and to facilitate needle entry into the cyst. Ultrasound can help to avoid neurologic or vascular structures when ganglia are located near them.²¹ Place the patient on a gurney with the hand on a bedside procedure table. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. It is recommended to provide local anesthesia for patient comfort, although the cyst can be aspirated and/or injected without anesthesia. Place a subcutaneous wheal of local anesthetic solution immediately over or adjacent to the periphery of the ganglion.

TECHNIQUE

GANGLION ASPIRATION

Manipulate the area to expose more of the cyst and facilitate needle entry into the cavity. Ultrasound may be used to delineate the cyst but is usually not necessary for the palpated ganglions.

Use sterile technique. Insert a 16 or 18 gauge needle on a 5 or 10 mL syringe through the anesthetized tissue and into the ganglion cyst cavity (**Figures 130-2 and 130-3A**). Apply negative pressure to the syringe to aspirate the cyst contents once the tip of the needle is within the cyst cavity (**Figure 130-3B**). Aspiration may require more force than anticipated as the mucinous contents of the cyst are quite viscous. The cyst can be manipulated and compressed to express more of the contents into the syringe once the very viscous clear or yellow material begins to flow into the syringe. Approximately 1 to 2 mL of fluid can be aspirated from a typical ganglion. Withdraw the needle when fluid can no longer be aspirated (**Figure 130-3C**). Apply a simple dressing. A pressure dressing may also be temporarily applied. **Take care not to compromise neurologic or vascular function with the pressure dressing.**

GLUCOCORTICOID INJECTION

The injection of glucocorticoids into a ganglion cyst immediately after aspiration is commonly recommended. One small study showed glucocorticoid injections decreased recurrence rates compared to aspiration alone.²² The literature has not yet shown a clear benefit.²³ Securely hold the aspirating needle in place after the cyst contents have been aspirated into the syringe. Remove the syringe. Do not move the needle. Attach a second syringe containing 10 to 15 mg of the glucocorticoid solution onto the needle. Aspirate to confirm the tip of the needle is not within a vascular structure. Inject the glucocorticoid solution into the cyst cavity. Withdraw the needle and apply a simple dressing.

ALTERNATIVE TECHNIQUES

Other variations of ganglion cyst aspiration and injection have been described in the literature. The injection of hyaluronidase into the cyst, with or without corticosteroids, has shown favorable results.^{24,25} Puncturing the ganglion wall at multiple separate locations has not been proven to decrease the recurrence rate when compared to aspiration at a single point alone.²⁶ Injection of hypertonic saline and other sclerosing agents (e.g., 1 mL of 3% sodium tetradecyl sulfate) has been suggested. Applying blunt force trauma to the cyst with a large book or other heavy object is a common home remedy with many anecdotal reports of success without recurrence.²⁷ Further study is necessary before these techniques can be recommended for widespread use in the Emergency Department.

ASSESSMENT

Patients usually report total or near-total relief of their symptoms immediately after aspiration. Obtaining highly viscous clear or yellow fluid from the cyst virtually confirms the diagnosis. Obtaining purulent fluid suggests a skin abscess and not a ganglion cyst. Failure to obtain fluid does not rule out the diagnosis of a ganglion. It should prompt an evaluation for alternative diagnoses.

AFTERCARE

Reassure patients that ganglia are not malignant tumors. Temporary immobilization (i.e., < 24 hours) of the affected limb may be performed for patient comfort. Splinting limits the ability of patients to function normally and does not appear to affect recurrence rates.²⁸ Instruct the patient to return to the Emergency Department for any significant increase in pain, erythema at the site or up the extremity, swelling beyond the ganglion's original size, purulent discharge, continued bleeding, or the development of a fever. Instruct the patient to elevate the extremity, avoid strenuous activity of the affected limb, and rewrap the pressure dressing if one is applied to

make it snug but not uncomfortable. Recommend acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) for relief of mild postprocedure pain. Narcotic analgesics are not required nor recommended. Oral corticosteroids have not been demonstrated to play a role in ganglion therapy.

Inform all patients with ganglion cysts aspirated in the Emergency Department of the potential for recurrence and the possibility of definitive ganglion treatment by surgical excision.^{8,29} Provide a referral to a Hand Surgeon if desired by the patient. The most effective therapy for ganglion cysts is believed to be open excision, although reports of postsurgical recurrence rates vary widely.³⁰ The Hand Surgeon removes the cyst and the stalk or pedicle that connects it to the normal synovium. Arthroscopic removal of wrist ganglia has also been described and performed successfully.^{6,31}

COMPLICATIONS

Complications of ganglion cyst aspiration are uncommon. They include bleeding and infection. Bleeding is self-limited and easily controlled with manual pressure. The use of sterile technique will minimize any infectious complications (e.g., abscess, cellulitis, or septic arthritis). Rare complications of corticosteroid injection include localized depigmentation that is due to injection outside of the cyst capsule or leakage out of the cyst capsule through the needle tract.³² Subcutaneous infiltration of glucocorticoids can result in fat atrophy, skin atrophy, and skin dimpling from fat atrophy.

SUMMARY

Ganglion cysts are common growths of the wrist and hand. They frequently enlarge to cause pain, sometimes to the point of disability. Contraindications to the aspiration of a ganglion cyst in the Emergency Department are few. The procedure is often warranted due to debilitating pain, deformity, or inability on the patient's part to promptly seek the care of a surgical specialist. The procedure is simple, quick, and only slightly uncomfortable. The injection of steroids into the cyst is commonly advocated to prevent recurrence. The efficacy of steroid injection has not been conclusively demonstrated. Ganglia recurrence is very common after aspiration and may occur even after surgical excision. **This fact must be clearly relayed to the patient.** All patients should be offered referral to a Hand Surgeon on a nonemergent basis to discuss further intervention.

Subcutaneous Abscess Incision and Drainage

Priya Perumalsamy

INTRODUCTION

Subcutaneous abscesses are commonly seen in the Emergency Department. Approximately 3% of patients present with this chief complaint.^{1,2} Abscesses occur in numerous anatomic areas with varied etiology and bacteriology. **An abscess is a tender and fluctuant mass located in the dermal or subdermal tissue.** It usually demonstrates the classic inflammatory responses of rubor, tumor, dolor, and calor. The abscess is usually tender. **The surrounding and underlying tissue should not be tender.**³⁻⁵

Incision and drainage is the definitive treatment of a simple soft tissue abscess.⁵⁻⁷ This procedure results in significant improvement in symptoms and a rapid resolution of the infection in uncomplicated cases.⁸ The addition of antimicrobial therapy is needed for

systemic signs of sepsis, immunocompromised patients, if source control is incomplete, and for abscesses with significant cellulitis.⁵ Premature incision before localization of pus will not be curative and may be deleterious. Oral antibiotics and warm compresses may be of value in helping the infection to coalesce in cases of immature abscesses or cellulitis. These methods are not a substitute for incision and drainage and should not be continued for more than 24 to 36 hours without a reassessment of the patient. The role for ancillary antibiotic use has come into question with the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA).

ANATOMY AND PATHOPHYSIOLOGY

PATHOGENESIS

An abscess is a localized collection of pus caused by suppuration buried in a tissue, organ, or confined space.⁹ Intact skin is very resistant to bacterial invasion. Localized pyogenic infections are usually initiated by a breakdown in the normal epithelial defense mechanisms in the normal host. Plugging of the ducts of a superficial exocrine gland may initiate the process. Occlusion prevents desquamation and provides a moist environment for organisms to proliferate. The combination of a high concentration of organisms, the presence of nutrients, and sufficient damage to the corneal skin layer to allow organisms to penetrate the skin defenses results in abscess formation.^{10,11}

Subcutaneous abscesses typically begin as a cellulitis with organisms that cause necrosis, liquefaction, and accumulation of leukocytes and debris. Early stages appear as an area of hyperemia and tender inflammation that later becomes fluctuant as an exudate of leukocytes, necrotic material, and cellular debris accumulates. This is followed by loculation and walling off of the pus. This progresses and the area of liquefaction increases until it “points” and eventually ruptures through the area of least resistance.⁴ **A simple abscess should not extend into deeper tissues or have multiloculated extension.** The induration and erythema are limited to a defined area of the abscess. An abscess with extensive overlying cellulitis, multiloculated extensions, or systemic signs of illness can be considered complex in comparison to a simple abscess.⁵

The body area involved depends upon host factors (e.g., drug use, employment-related exposures, or minor trauma).^{5,11-13} Areas with a compromised blood supply are more prone to infection as normal host cell-mediated immunity is not as available.¹¹ Soft tissue infections most commonly affect the lower extremities, perineum, and abdominal wall.⁵

BACTERIOLOGY

Most abscesses are polymicrobial with the isolated organisms usually representing the normal resident flora associated with the body area on which the abscess is found.^{10,13-15} Nonresident bacteria are found in abscesses that occur from direct inoculation of extraneous organisms (e.g., following human bite wounds, intravenous drug use, or bacterial seeding of embedded foreign bodies).¹⁶ Most infections involving healthy skin are caused by gram-positive cocci, most commonly *S. aureus* and group A *Streptococcus*.^{5,13,15} Anaerobes are found in all areas of the body but predominate in abscesses of the buttocks and perirectal regions.^{14,17}

S. aureus is present as a single pathogen in only 25% of cutaneous abscesses.¹³ Community-acquired MRSA (CA-MRSA) is presently considered to be the most common identifiable pathogen causing abscess at major centers.^{18,19} CA-MRSA is defined as infection with MRSA acquired in the community lacking the traditional risk factors of hospital-acquired MRSA (e.g., a recent stay in a long-term care facility or in a day care setting, recent health care contacts

or surgery, an indwelling device, dialysis, immunosuppression, chronic illness, or recent antibiotic use).^{13,20-22} Patients at a higher risk of acquiring MRSA infections include those with recent household or daycare contacts, children, men who have sex with men, those in the military, incarcerated patients, athletes who participate in contact sports or share equipment, Native Americans, Pacific Islanders, patients with previous MRSA infections, and intravenous drug users.^{13,20-24} It is essential not to exclude MRSA in the absence of risk factors.¹⁸ Investigate patients presenting with a complaint of a “spider bite” for MRSA.^{20-22,25} MRSA was isolated from abscesses in 51% of patients.²⁶ An American study of academic centers in 2006 found MRSA incidence rates as high as 60% in patients presenting with skin and soft tissue infections.²⁷ Up to 77% of MRSA-related illnesses are skin and soft tissue infections.²⁸

In the United States, 98% of CA-MRSA strains carry the *mecA* gene, which is thought to impart the antimicrobial resistance. This is carried on the staphylococcal cassette chromosome type-IV which is distinct from other forms of MRSA.^{20-22,29} Most have the gene for Panton-Valentine leukocidin (PVL), an exotoxin that predisposes patients to cutaneous infections.^{21,22,29} PVL has been identified in up to 95% of CA-MRSA cases.²⁹ PVL-positive strains are associated with tissue necrosis and abscess formation.²⁰

Up to 17% of abscesses are sterile.^{8,10,17} Nearly 40% of these are secondary to intravenous drug use and most likely result from injection of necrotizing chemical irritants.³⁰ Viruses (e.g., herpes), auto-immune mechanisms, or systemic illnesses (e.g., benign tumors, metastatic tumors, and granulomatous disease) may cause sterile abscesses.^{3,31} These atypical etiologies may present with an exacerbation of the underlying disease process in the absence of local inflammatory signs and symptoms.

SPECIFIC CLINICAL ENTITIES

Furuncles, or boils, are acute circumscribed abscesses of the skin and subcutaneous tissue that most commonly occur on the axilla, breast, buttocks, face, neck, perineum, and thigh. Carbuncles are aggregates of interconnected furuncles that frequently occur on the back of the neck where the thick skin causes lateral extension of the infection rather than pointing toward the skin surface. These occur with a higher frequency in diabetics. They can be large and cause systemic signs, symptoms, and complications. Carbuncles often require surgical consultation and treatment in the Operating Room.

Hidradenitis suppurativa is a chronic relapsing inflammatory disease process affecting the apocrine glands primarily in the axilla, the inguinal region, or both.³² This process initially will appear like a typical abscess and is only identifiable in its chronic scarring phase when there are multiple lesions with tender areas of induration and inflammation in various stages of healing. The chronic process leads to draining fistulous tracts that require ongoing surgical management. Emergency Department management involves the usual incision and drainage procedure of any area of fluctuance. Patients should be informed that the intervention is not curative and that the problem is chronic. Arrange a referral to a General Surgeon, Dermatologist, or Plastic Surgeon for long-term follow-up.

Up to 80% of breast abscesses occur in nonlactating women.³ Peripheral and superficial lesions are similar to abscesses elsewhere on the body. They respond to conservative incision and drainage with an incision that radiates out centripetally from the nipple.³³ Deeper and periareolar abscesses are often complex and require surgical referral and general anesthesia to properly treat. Postpartum mastitis is common and precipitated by milk stasis and bacterial invasion through a cracked nipple. The offending organism is commonly *S. aureus* or *Streptococcus* species. Treatment includes the application of heat, oral antibiotics, and continued breast emptying with a breast pump or feeding of the baby. The mastitis may evolve

into an abscess and is often associated with systemic symptoms. Appropriate antibiotic therapy and follow-up in 24 to 48 hours are required.

Sebaceous cysts are a common cause of a subcutaneous abscess. They can persist for long periods as nontender subcutaneous swellings before becoming infected. They appear like most other abscesses. Sebaceous cysts can be identified by a small punctate sinus tract near the center of the fluctuant area. The initial treatment is incision and drainage. The contents are usually thick cheesy material that needs to be manually expressed. A sebaceous cyst has a definite shiny white capsule that must be excised at the time of incision and drainage or at the first follow-up visit to prevent recurrence. The area is then treated as any other healing abscess cavity.

The recurrence of an abscess that has been previously drained should suggest the possibility of underlying osteomyelitis, a retained foreign body, or the presence of unusual organisms such as mycobacteria or fungi. Recurrent abscesses should prompt further investigation including an assessment of the patient's immune status.

SPECIAL CONSIDERATIONS

The precise risk for endocarditis associated with subcutaneous abscesses is unknown. Up to 5% of patients with abscesses have bacteremia at the time of presentation.^{3,34} Incision and drainage of cutaneous abscesses can result in transient bacteremia with the organism causing the abscess.^{8,35,36} The clinical relevance of this bacteremia has become controversial.³⁴ **Only patients considered to be at high risk for endocarditis are recommended to receive antimicrobial prophylaxis before incision and drainage (Table 131-1).**³⁷ Direct bacterial endocarditis prophylaxis at the most likely pathogen causing the infection. An antistaphylococcal penicillin or a first-generation cephalosporin is an appropriate choice for most soft tissue infections (Table 131-2). Clindamycin is an acceptable alternative for patients allergic to penicillin. Patients with immunodeficiency and localized soft tissue abscesses may be at higher risk for developing septicemia secondary to bacteremia induced by incision and drainage, but it is unclear if they are at higher risk of complications and death.^{38,39} These patients may benefit from prophylactic antibiotics prior to incision and drainage, but only indirect evidence is available and no controlled studies have been done.⁴⁰ **High-risk patients with known or suspected MRSA infection should receive intravenous vancomycin or clindamycin when undergoing incision and drainage.**³⁷

PATIENT ASSESSMENT

Take a focused history and assess for trauma, intravenous drug use, history of fever, and past medical history. Inquire about diabetes, renal failure, steroid use or other immune suppression, peripheral vascular disease, and valvular heart disease. It is important to note any risk factors for CA-MRSA as this may alter management of certain patient populations.⁴¹ Past anesthetic history and

TABLE 131-1 Cardiac Conditions at Risk for Endocarditis That Require Antibiotic Prophylaxis for Incision and Drainage³²

Cardiac transplant with cardiac valvulopathy
Prosthetic cardiac valves, including bioprosthetic and homograft valves
Previous bacterial endocarditis
Repaired congenital heart disease (CHD) with prosthetic material or device within 6 months after the procedure (regardless of method of placement)
Repaired CHD with residual defects at or adjacent to site of prosthetic patch or device
Unrepaired cyanotic CHD, including palliative shunts and conduits
Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD

TABLE 131-2 Prophylactic Antibiotic Regimens³²

Clinical situation	Agent	Dose*	Timing
Standard general prophylaxis	Amoxicillin	Adults: 2.0 g Child: 50 mg/kg	PO, 30–60 min prior to the procedure
Unable to take oral medications	Ampicillin	Adults: 2.0 g Child: 50 mg/kg	IV or IM, 30 min prior to the procedure
Unable to take oral medications	Cefazolin or ceftriaxone	Adults: 1.0 g Child: 50 mg/kg	IV or IM, 30–60 min before procedure
Allergic to penicillin or ampicillin	Cephalexin†	Adults: 2.0 g Child: 50 mg/kg	PO, 30–60 min prior to procedure
Allergic to penicillin or ampicillin	Clindamycin	Adults: 600 mg Child: 20 mg/kg	PO, 30–60 min prior to procedure
Allergic to penicillin or ampicillin	Azithromycin or clarithromycin	Adults: 500 mg Child: 15 mg/kg	PO, 30–60 min prior to procedure
Allergic to penicillin and unable to take oral medications	Cefazolin† OR Ceftriaxone	Adults: 1.0 g Child: 25 mg/kg	IV or IM, 30–60 min prior to procedure
Allergic to penicillin and unable to take oral medications	Clindamycin	Adults: 600 mg Child: 20 mg/kg	IV or IM, 30–60 min prior to procedure
Known or suspected MRSA	Vancomycin	Adults: 1 g Child: 20 mg/kg	IV, 30 minutes prior to procedure

IM, intramuscular; IV, intravenous; PO, oral.

*Total child dose should not exceed adult dose.

†Cephalosporins should not be used in patients with immediate-type hypersensitivity reactions (e.g., urticaria, angioedema, or anaphylaxis) to penicillin.

the potential for aspiration should be assessed if procedural sedation (Chapter 159) is to be considered.⁴² Ask about medications and allergies. The patient's tetanus status must be confirmed and booster doses provided as required.

A brief physical examination documenting function and intact distal neurovascular status of extremities involved is required. Evidence of pain on passive or active movement of fingers may suggest a deep space infection.³ A high index of suspicion is required, especially in injection drug users, to identify those seemingly simple cutaneous infections that unpredictably evolve into extensive necrotizing soft tissue infections.^{41,43} General assessment of the airway and cardiopulmonary system, vital signs, and mental status is indicated if procedural sedation (Chapter 159) is to be employed.⁴²

Routine laboratory studies are not indicated in otherwise healthy individuals. Consider a complete blood count looking for leukopenia or toxic granulations in immunocompromised patients. Diabetics should have electrolytes, blood urea nitrogen, creatinine, and glucose assessed. Elevated potassium in diabetics may indicate myonecrosis.⁴⁴ Consider a urinalysis for myoglobinuria. Consider obtaining radiographs of the affected areas if there is a history of trauma, drug use, or concern regarding a deep infection. Abscesses in injection drug users may be contaminated with foreign bodies (e.g., broken needles). Foreign bodies and fractures may not be easily identifiable because of the edema and tenderness caused by the infection.^{5,45} Gas or osteolytic lesions on plain radiographs may indicate severe deeper infection, the need for urgent surgical consultation, and prompt antibiotic therapy.⁴⁵ Vascular complications should also be considered based on the site and evaluated with duplex sonography if needed. A further evaluation for endocarditis is necessary if there are persistent signs of sepsis.⁵

Culturing the purulent material from a drained abscess was previously considered to be of little value. Controversy exists today as to the value of culture in abscess management. Although many experts suggest it is of little value because it has no bearing on acute management,^{7,46–48} others suggest it is vital to help determine antimicrobial susceptibility and outbreak patterns.^{5,25,41} **Obtain cultures because they may alter later management in cases of recurrent or refractory infections, patients who are seriously ill, immunocompromised, patients on an antimicrobial with variable activity,**

patients who have failed surgical treatment, and any patient being admitted to the hospital.^{5,25,41,49} Gram's stain and cultures for both aerobic and anaerobic bacteria may be helpful in patients who are febrile, systemically unwell, or immunocompromised, or who present atypically.^{5,41,50,51}

ULTRASONOGRAPHIC EVALUATION

Bedside ultrasound (US) use in the Emergency Department is of great value in evaluating skin and soft tissue infections.⁵² US can be used to differentiate a cellulitis from an abscess in difficult cases. There are numerous advantages to using US (e.g., portability, inexpensive, comfortable for patients, and no radiation exposure). It is fast and easy to gain proficiency for specific applications.⁵³ US is indicated for ambiguous physical findings (e.g., widespread cellulitis), localizing an incision site, and ruling out dangerous masses (e.g., a pseudoaneurysm that masquerades as an abscess).⁵⁴ US is helpful in identifying small or early abscesses, deep abscesses, abscesses under previous scars, and for localizing adjacent major vessels or nerves.^{54–59} US has a sensitivity of 98% and specificity of 88% in detecting an abscess.⁵³ Another study noted a sensitivity of 87% and a specificity of 72% overall.⁶⁰ The numbers were better when the clinical examination was sure there was an abscess present and worse if not. Studies of presumed cellulitis in the Emergency Department found that US changed the case management because swelling thought to be due to cellulitis can hide an abscess.^{52,57,61} US is useful in evaluating cellulitis in children and determining if an incision and drainage is necessary.⁶² US can be used to guide an aspiration, to confirm the presence of an abscess, and to obtain material for culture and Gram's stain.⁶³

It is important that the Emergency Physician has an appreciation of the anatomic structures of the area. The location and sonographic appearance of arteries, veins, nerves, and tendons should be known before the incision and drainage procedure. A 5 to 7.5 MHz linear array transducer is generally used. Some find a standoff pad or gel-filled glove to be useful for superficial structures.^{54,64}

Scan the area of infection in two orthogonal planes.^{54,61} Lower frequency transducers are useful for deeper abscesses, whereas higher frequency transducers are more effective for superficial abscesses.

FIGURE 131-1. Ultrasound image of a breast showing cobblestoning of the subcutaneous tissue indicative of edema secondary to cellulitis with echogenic material surrounded by echo-poor areas consistent with early abscess formation.

It is important to use transducer covers as well as proper cleaning and disinfecting supplies to avoid cross-contamination.

Differentiation between a cellulitis and an abscess is based on several findings. Cellulitis shows diffuse hyperechogenicity and thickening of the skin and subcutaneous fat. Echo-poor strands between hyperechoic fatty lobules in the subcutaneous tissue is known as cobblestoning and is indicative of cellulitis (**Figure 131-1**).^{53,54,59,63} An abscess has a wider array of presentations on US. An abscess is most frequently a spherical- or elliptical-shaped anechoic or echo-poor region with sharper echogenic borders (**Figure 131-2**).^{54,65} Within the echo-poor area there may be gas, lobulations, septations, and echogenic debris. There are some cases where the abscess can appear to be isoechoic or hyperechoic. There may be a role for US-guided aspiration in these cases.⁶⁵ Gentle digital palpation or pressure may induce motion of the purulent material within the abscess if unsure if an abscess is present on US.⁶⁵ Posterior acoustic enhancement can be seen in the presence of an abscess.⁵⁴ This technique can help rule out similarly presenting hematomas, necrotic tumors, vascular lesions, or schwannomas.⁶³ There is an emerging role for Doppler US in abscess evaluation. The findings of increased

FIGURE 131-2. Ultrasound image showing a large hypoechoic area representing a large superficial abscess.

FIGURE 131-3. Color Doppler ultrasound image showing peripheral hyperemia around a large abscess cavity.

vasculature, peripheral blushing and hyperemia, and increased large vessel flow around the abscess are common (**Figure 131-3**).⁶⁶

INDICATIONS

The presence of a fluctuant mass in an area of induration, erythema, and tenderness is clinical evidence that an abscess requires incision and drainage. Antimicrobial treatment without incision and drainage can lead to treatment failures in patients with abscesses.⁶⁷ Examination alone may not definitively indicate an abscess, especially if it is deep. This can be further confirmed by bedside US, with or without needle aspiration.³ Obtaining purulent material on aspiration identifies an abscess and is an indication for incision and drainage.³ Oral antibiotics, warm compresses, and follow-up in 24 hours must be arranged for a reassessment if no pus is aspirated.

CONTRAINDICATIONS

The only absolute contraindication to the incision and drainage of an abscess is the possible association with a mycotic aneurysm.^{12,44} Abscesses commonly overlie large vessels (e.g., the anterior triangle of the neck, the supraclavicular fossa, the deep space of the axilla, the antecubital fossa, the groin, and the popliteal space).⁶⁸ Fine-needle aspiration for blood, diagnostic imaging, and/or angiography are indicated prior to incision and drainage in these locations or if the abscess is pulsatile.

Relative contraindications to incision and drainage are common. It includes an inability to achieve adequate anesthesia. An abscess associated with a deep foreign body that requires additional real-time imaging (e.g., fluoroscopy or US) may require surgical referral.⁶⁹ Proximity of an abscess to important neurologic, tendinous, or vascular structures may require specialty consultation and magnification in the Operating Room. Deep space infections or involvement of any joint requires admission for parenteral antibiotic therapy and possible operative debridement. Patients presenting with soft tissue infections exhibiting pain out of proportion to physical examination findings or deep anesthesia of the involved or distal area should raise the possibility of deeper infections (e.g., necrotizing fasciitis or myonecrosis).⁴⁵ Perirectal and periurethral abscesses are often larger and deeper than they appear and may be complicated by sinus tracts that require exploration under general anesthesia. Manipulation of abscesses in the “danger triangle” of the face (i.e., the corners of the

mouth to glabella) can lead to septic thrombosis of the cavernous sinus. Periorbital or orbital abscesses require a consult from an Ophthalmologist for an assessment and treatment.

EQUIPMENT

■ ANESTHESIA

- 18 and 27 gauge needles, 1½ inches long
- 10 mL syringes
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution with epinephrine
- Local anesthetic solution without epinephrine if abscess is near an end arteriolar system
- Ethyl chloride spray
- Ice pack

■ PROCEDURE

- #11 and #15 scalpel blades on a handle
- Hemostats in two sizes for breaking up loculations and probing the cavity
- Scissors
- Normal saline
- 10 or 20 mL syringe with a 20 or 22 gauge angiocatheter
- Suction source, tubing, and catheter for larger abscesses
- 4×4 gauze squares
- Iodoform gauze packing
- Adhesive tape
- Culture swabs and vials
- US machine
- A 5 to 7.5 MHz transducer
- US transducer covers
- US gel
- Standoff pad
- US transducer cleaning and disinfecting solutions

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. **Patients should be warned of potential cosmetic complications prior to proceeding.** Obtain an informed consent to perform the procedure. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Oral regimens should be given 1 hour prior to the procedure and parenteral regimens within 30 minutes of the procedure if endocarditis prophylaxis is indicated (Table 131-1).

Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Apply drapes to delineate a sterile field. Many Emergency Physicians regard this last step as optional. **The procedure of cutting into a contaminated abscess is done cleanly and not sterile.**

ANESTHESIA

It is usually possible to achieve adequate anesthesia for the skin incision, but any additional manipulation may be painful.⁷⁰ Local anesthetic infiltration is often less effective than in other procedures. The

pH of infected tissue is often low and retards the diffusion of the local anesthetic solution into nerve axons.⁷¹ A regional field block can be instituted by injecting a ring of 1% lidocaine or 0.5% bupivacaine subcutaneously approximately 1 cm away from the perimeter of the erythematous border of the abscess. The onset of anesthesia occurs after about 5 minutes. A small amount of local anesthetic solution can be injected intradermally into the roof of the abscess in a linear fashion along the line of the planned incision (Figure 131-4A).³ **Be careful during this portion of the procedure as the abscess may be under pressure. The inadvertent injection of local anesthetic solution into the abscess cavity may cause fluid to be forcibly ejected toward the Emergency Physician. Appropriate universal precautions should be employed including a face mask and eye protection.** The use of a transdermal lidocaine-tetracaine patch (Synera; Chapter 154) provides equal analgesia to injection of lidocaine.⁷² Consider using this patch for the incision and drainage of an abscess.

Topical ethyl chloride spray can be used to provide anesthesia for superficial abscesses or furuncles which are unlikely to require significant exploration. Invert the bottle and compress the spray nozzle to begin the flow of fluid. Direct the spray toward the planned site of incision. The pain relief from ethyl chloride is variable and fleeting. It is also highly flammable.⁴ The application of an ice pack over the planned incision site secured with an elastic bandage for 15 minutes can also be effective. This may be especially useful for children, patients with severe needle phobias, or in cases of a true anesthetic allergy.

Nitrous oxide is safe and was previously thought to be effective as an adjunct to the incision and drainage of abscesses.⁷³ More recently, it has been shown to cause no significant reduction in pain and to only be marginally effective as an anxiolytic.⁷⁴ Procedural sedation (Chapter 159) can be useful in deep abscesses that require extensive probing.⁷⁵ It is difficult to obtain adequate pain control with a field block.

TECHNIQUES

ASPIRATION

Aspiration is performed as a diagnostic procedure in cases of soft tissue infections where the presence of an abscess is unclear, a mycotic aneurysm must be ruled out, or samples for Gram's stain and culture are required. **Aspiration is not a therapeutic procedure.** Anesthetize the skin. If US is available, locate the abscess cavity and determine the shortest needle path. Insert an 18 gauge needle attached to a 10 mL syringe into the skin. The needle appears as a bright, hyper-echoic line with posterior reverberation artifact.⁶³ The needle will become increasingly oblique as it penetrates deeper. Apply negative pressure to the syringe.

Advance the needle into the area where pus or blood is presumed to be loculated. Terminate the US-guided aspiration and perform an incision and drainage if pus is obtained. Inoculate anaerobic and aerobic culture bottles directly from the syringe if cultures are indicated. Simple swabbing of the purulent material after incision and drainage is inadequate for growth of anaerobic organisms. Blood aspirated signifies that the needle tip is in a vascular structure. **Terminate the procedure and apply firm pressure to the area to prevent a hematoma from forming if blood is aspirated.** Angiography with surgical consultation should immediately follow. Redirect the needle in several directions to confirm the absence of an abscess if no pus or blood is aspirated. Discharge the patient with oral antibiotics, warm compresses, and instructions to follow-up in 24 hours for a reassessment.

INCISION AND DRAINAGE

Make an incision spanning the entire area of fluctuance and parallel to the relaxed skin tension lines to reduce scarring.^{44,76} A straight incision with a #11 scalpel blade is usually performed

FIGURE 131-4. Incision and drainage of a subcutaneous abscess. **A.** Infiltration of local anesthetic solution over the abscess. **B.** A straight incision to drain the abscess. **C.** An elliptical incision to drain the abscess. **D.** The wound is irrigated with sterile saline. Any pockets of pus are opened by blunt dissection with the hemostat. **E.** The wound is packed open.

(**Figure 131-4B**). An elliptical incision with a #15 scalpel blade is an alternative and often results in a similar-appearing final scar (**Figure 131-4C**). The purpose of the elliptical incision is to remove a full-thickness wedge of tissue so that the wound will remain open. **Do not make an elliptical incision in cosmetically sensitive areas (e.g., face, neck, or breasts) or in areas with minimal subcutaneous tissue (e.g., hands and feet). Ensure a large enough incision is made to promote adequate drainage except for cosmetically sensitive areas where a stab incision may be initially attempted to limit scar formation.**⁴

Debride any necrotic or devitalized tissue. Probe the cavity by inserting a hemostat. Gently spread the jaws open to break up any loculations and to release any further pockets of purulent material (**Figure 131-4D**).⁶ Rotate the hemostat around the entire abscess to break any loculations. **Do not use a scalpel for the blunt dissection of an abscess cavity as it may cause additional tissue damage and bacteremia.**⁷⁷ Remove the tough shiny capsule by grasping the edges with a hemostat and applying firm traction if the abscess is due to an infected sebaceous cyst. The capsule can often be removed intact.

Irrigate the abscess cavity with an 18 gauge angiocatheter attached to a 10 mL syringe containing sterile saline (**Figure 131-4D**). An alternative is the Splash Cap (BSN Medical Inc., Charlotte, NC). The advantages of this device are that it attaches to saline bottles, is disposable, and shields from contaminated spray when irrigating (**Figure 131-5**). This will flush away all loosened purulent and necrotic material.

Loosely pack iodoform gauze into the abscess cavity (**Figure 131-4E**).⁷⁶ Leave 1 to 2 cm of gauze exiting from the cavity to prevent the incision from sealing over and ensure an adequate drainage tract for the cavity. The value of antiseptic impregnated gauze over plain gauze is uncertain. Do not overpack the abscess cavity as this may interfere with the inflammatory hyperemia necessary for healing, retard

drainage, and reproduce “abscess-like” conditions.⁶ Apply an absorbent dressing of 4×4 gauze over the wound. Splinting and elevation of the affected area may be beneficial in select patients (e.g., young patients and confused patients).

FIGURE 131-5. A Splash Cap on a saline bottle. (Photo courtesy of Joseph Schultz, MD.)

LOOP DRAINAGE TECHNIQUE

The loop drain technique confers several advantages over the traditional incision and drainage. Smaller incisions result in better cosmesis. The incision drains while the loop is in place and eliminates packing changes. This is especially beneficial in the pediatric population for whom packing changes and wound care may be difficult. A drain will be needed in addition to the usual equipment. This can be a silicone vessel loop, a small Penrose drain, a sterile rubber band, sterile suture, or a piece of a sterile glove.⁷⁸

The skin is cleaned, draped, and anesthetized in the usual fashion. Make an initial 0.5 to 1 cm incision at one end of the abscess and if possible where the abscess is pointing. Use a hemostat to break up any loculations (Figure 131-6A). Express as much pus as possible. Obtain cultures if clinically indicated. Use the hemostat to probe the abscess and tunnel through until the opposite end of the cavity is reached. Continue to express any pus present.

Tent the skin and make a second incision over the tip of the hemostat (Figure 131-6B). The distance between the two incisions should only be a few centimeters. Irrigate the wound with sterile saline. A syringe and plastic catheter will provide adequate pressure for irrigation. An alternate is to use a Splash Cap (Figure 131-5).

Insert the drain. Use the hemostat to pull the drain through the second incision and exit the first incision (Figures 131-6C and 131-6D). The drain should be under the skin and traverse the length of the abscess cavity. Tie the two loose exposed ends of the drain in a loose loop. Use a finger or a syringe as a placeholder to avoid excessive skin tension when the tying the loop (Figure 131-6E). Tie multiple knots to secure the drain (Figure 131-6F). Remove the syringe, if used, and trim the excess free ends of the drain. Large or irregularly shaped abscesses will need multiple loops for adequate drainage (Figure 131-7). Cover the skin puncture site with gauze.

AFTERCARE

Most available evidence suggests that incision and drainage of subcutaneous abscesses alone is adequate treatment and additional antimicrobial therapy is unnecessary in healthy patients with no major comorbidities.^{7,47,48,79-81} Many recent studies involving abscesses, including those caused by MRSA, have demonstrated that patients have similar outcomes regardless of whether appropriate antibiotics were used after an abscess incision and drainage.^{18,28,82-84} Pediatric studies have shown no difference in treatment failure based on the size of an abscess or surrounding cellulitis.

Treatment failure was higher in those presenting with fever and age less than 1 year.⁸⁵⁻⁸⁷

Antimicrobial therapy should be considered if systemic signs of sepsis are present, in immunocompromised patients, if the source control is poor, in patients with multiple abscesses, in patients at the extremes of age, in patients with a lack of response to incision and drainage, or if there is significant cellulitis.^{5,22,50,51,85} Consider MRSA-specific antibiotics for patients at risk for MRSA.^{5,50,51} Recommendations from the Centers for Disease Control and Prevention suggest antibiotics after incision and drainage in patients with rapid progression, comorbidities (e.g., diabetes mellitus), human immunodeficiency virus, or neoplastic disease; patients at extremes of age; patients with abscesses in locations that are difficult to drain or that have a risk of septic phlebitis associated with it; and in patients who fail to respond to incision and drainage alone.^{22,88} Pediatric patients with abscesses greater than 5 cm should also receive empiric antimicrobial therapy.⁸²

Many oral antibiotics (e.g., cephalexin, dicloxacillin, and trimethoprim-sulfamethoxazole) can be a good first choice for healthy individuals in areas where the prevalence of MRSA is extremely low.^{22,51,89} **Knowledge of local MRSA prevalence and antimicrobial**

susceptibility patterns is paramount when selecting the appropriate antibiotic.^{22,44,50,51} Empiric treatment with agents that show activity against MRSA is warranted if more than 10% to 15% of community *S. aureus* isolates are MRSA.⁹⁰⁻⁹² US may be used to identify those abscesses that are caused by MRSA (e.g., ill-defined edges, indistinct, irregular shaped, or small).^{93,94} Current guidelines for outpatient therapy suggest using trimethoprim-sulfamethoxazole, clindamycin, doxycycline, minocycline, or linezolid.^{51,89,92} Intravenous therapy for patients with significant comorbidities and signs of systemic infection should include clindamycin, ceftaroline, daptomycin, linezolid, tigecycline, or vancomycin.^{50,51,95} Clindamycin, doxycycline (if over the age of 7 years), or trimethoprim-sulfamethoxazole is recommended in healthy children.⁹⁶ Guide antibiotic selection using the current literature and consideration of the local antibiotic resistance patterns.^{22,51,97} Administer antimicrobial therapy for at least 5 days. Consider extended treatment or a different regimen if the infection has not improved in 5 days.⁵¹

The patient should follow up in 24 to 48 hours to remove the packing and assess the response to therapy. Pain can be adequately controlled with the use of acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). Narcotic analgesics are rarely required. Instruct the patient to immediately return to the Emergency Department if they develop fever, chills, increased pain, increased swelling, or increased redness to the surrounding skin.

Repack the cavity approximately every 48 hours until granulation tissue develops throughout the wound and the drainage tract is well established if a large amount of drainage continues.^{98,99} At that time, the remaining packing is removed and the patient is instructed to soak the area in warm water three to four times per day.³⁰ Healing occurs in 5 to 9 days in most cases.^{3,6,30} The patient may be discharged from medical care when all signs of infection (e.g., erythema, drainage, pain, and induration) have resolved.

The aftercare with a loop drainage is easier than with the traditional incision and drainage. The patient can bathe and shower as usual. Continue warm compresses over the area. Change the dressing one to two times a day, or more frequently if saturated. Gently pull the loop daily to help keep the wound open. Remove the drain by cutting the loop and pulling it out when the drainage stops. The small incision sites will heal with better cosmesis than a large incision by secondary intention.^{100,101} The loop technique does not involve the pain of packing.⁷⁰ The abscess resolution and complications are similar to those of the traditional technique.¹⁰²

FIGURE 131-7. Large or irregular abscesses may require more than one loop. (Photo used with permission from reference 101.)

FUTURE ADVANCES IN ABSCESS MANAGEMENT

It is currently standard practice to pack an abscess cavity after an incision and drainage.⁵¹ Packing is used for hemostasis, to keep the abscess cavity from closing prematurely, and to debride the abscess cavity. **Packing an abscess cavity can be painful and requires multiple follow-up visits.** These visits are at an additional cost to the patient. Several small studies of noncomplicated abscesses found that not packing an abscess cavity resulted in less pain, less analgesic use, and no increased morbidity.¹⁰³⁻¹⁰⁶ To pack or not to pack an abscess cavity is up to the Emergency Physician and the informed patient. An elliptical incision or the loop technique does not require packing.

Incision and drainage of abscesses usually requires flushing of the abscess cavity. Irrigation of abscesses after incision and drainage did not improve outcomes.¹⁰⁷ The irrigation group in the small study was from a single site, younger, more often treated with packing, and treated with antibiotics, confounding results. Approximately only half of Emergency Physicians irrigate the abscess cavity even though it is recommended by guidelines.¹⁰⁸

Abscesses are currently allowed to heal by granulation. This process can take weeks and results in large scars. Primary suture closure after incision and drainage has been used around the world except in the United States.^{109,110} This treatment can reduce scarring, reduce pain, and promote faster healing. Most of the studies involved a small number of patients, administered preprocedural antibiotics, and were performed in the Operating Room. Further studies are required before this change in practice can be recommended for the Emergency Department management of abscesses.

DECOLONIZATION AND PREVENTION

Decolonization regimens after incision and drainage do not have established effectiveness.^{20,22,48} A decolonization regimen may play a role in patients with recurrent infections, patients not responding to therapy, or patients with a closely associated cohort at risk (e.g., infirm family, sports teams, or the institutionalized).⁴⁹ Colonization rates vary by geography and colonization is considered a risk factor for MRSA infection. Decolonization is not routinely recommended due to limited supporting evidence, poor patient compliance, and the risk of increasing antibiotic resistance.^{25,48,111}

Patient education is the most effective way to reduce the spread of infection and recurrent infections from MRSA.^{22,25,111} Maintaining a clean and dry wound, frequent handwashing and bathing, avoiding sharing any personal items, laundering clothing that has come into contact with the wound, avoiding skin to skin contact, and disinfecting equipment and other surfaces are essential recommendations that should be made to outpatients with MRSA skin and soft tissue infections.^{22,111}

COMPLICATIONS

Complications resulting from the incision and drainage of an abscess are uncommon. Scarring will result from deliberate open packing and secondary intention granulation of the wound. Infectious complications (e.g., inciting bacterial endocarditis) is possible. **Endocarditis can be avoided with appropriate screening of patients and the administration of prophylactic antibiotic therapy in patients at risk.** Precipitation of septicemia because of transient bacteremia in an immunodeficient patient must be considered prior to the procedure. Incision and drainage of a mycotic aneurysm should not occur if an appropriate assessment is completed prior to making the incision. The use of US with Doppler can determine the difference between an abscess and a vascular structure (**Figure 131-8**).

SUMMARY

Simple incision and drainage under local or regional anesthesia in the Emergency Department can effectively treat most subcutaneous abscesses. Adjunctive procedural sedation may be required to adequately probe a deep cavity. A directed history and physical examination will identify patients who may require additional lab work, imaging, specialty consultation, and follow-up. Most patients will not require antibiotics, although there may be a role for ancillary treatment in selected patients with MRSA infections. Attention must be paid to requirements for endocarditis prophylaxis and consideration given to the possibility of inducing bacteremia in any given patient.

Paronychia or Eponychia Incision and Drainage

Lisa R. Palivos and Tim Richardson

INTRODUCTION

A paronychia is inflammation of the soft tissue surrounding the nail plate, commonly caused by an infection or an abscess (**Figure 132-1**). It is the most common infection of the hand.^{1,2} A paronychia can be located on the fingers or the toes. It occurs in all age groups. It can cause significant pain and discomfort leading to a visit to the Emergency Department.

A paronychia initially presents with redness, swelling, and tenderness along the edges of the nail plate (**Figure 132-1**). This can progress to an abscess that requires drainage. An infection that extends to the overlying proximal cuticle is termed an eponychia. This chapter discusses the treatments which vary with the extent and the location of the infection.

ANATOMY AND PATHOPHYSIOLOGY

The dorsal aspect of the distal digit consists of the nail plate, the nail bed (i.e., matrix), and the perionychium (**Figure 132-2**). The nail bed is situated beneath the nail plate and is responsible for growth of the nail. The perionychium is the soft tissue surrounding the nail plate. It is composed of the eponychium proximal to the nail plate and the lateral nail folds.

A paronychia is usually the result of minor trauma to the seal formed by the nail plate and nail fold.³ This may occur from tight-fitting apparel (e.g., gloves, pantyhose, and shoes), aggressive manicures, the use of artificial nails, hangnails or ingrown nails, foreign bodies, or nail biting.^{3,4} The disruption of this seal allows bacteria to enter causing a localized cellulitis that may progress to abscess formation in the potential space between the nail plate and nail fold (**Figures 132-1 and 132-2**).^{1,5} A paronychia can grow and spread under the nail plate causing a subungual abscess. The infection may advance to the volar soft tissues and deep structures resulting in a felon, osteomyelitis, or tenosynovitis.⁶

Most paronychia are polymicrobial. They often contain a mixture of aerobic and anaerobic organisms.^{7,8} The most common

FIGURE 132-2. The distal finger illustrating a paronychia and the surface anatomy.

organism to cause a paronychia is *Staphylococcus aureus*.⁹ Paronychia are often caused by anaerobes secondary to finger sucking or nail biting in children and nail biters.¹⁰ Gram-negative organisms should be considered in immunocompromised hosts. The etiology of a chronic paronychia is complex and likely multifactorial. Patients are often colonized with *Candida albicans* but the infection is not likely the cause.¹¹ Chronic paronychia refractory to steroid and pathogen-directed therapies must be considered as result of a neoplasm (e.g., subungual melanoma or squamous cell carcinoma).¹²

INDICATIONS

An early paronychia will present with signs of cellulitis, redness, and tenderness without fluctuance of the nail fold. This may be treated nonsurgically with warm water soaks six to eight times per day using chlorhexidine or povidone solutions.¹³ The addition of oral antibiotics to cover *Staphylococcus*, plus anaerobic coverage if nail biting or finger sucking were causative, is recommended if symptoms persist.^{14,15} Amoxicillin-clavulanate, clindamycin, and trimethoprim-sulfamethoxazole are commonly used antibiotics. **The prevalence of methicillin-resistant *S. aureus* (MRSA) in your community will help decide the choice of antibiotics.**

A progression of the infection results in fluctuance and the formation of an abscess. The digital pressure test may be used to diagnose the presence of an abscess when the exam is otherwise equivocal. Instruct the patient to oppose the thumb and affected finger.¹⁶ Apply light pressure to the distal volar aspect of the affected digit. The skin under the nail plate will blanch if an abscess is present.¹⁷ **The presence of an abscess, fluctuance, or pus beneath the nail plate requires an incision and drainage procedure.** This procedure will relieve the patient's pain, promote healing, and prevent complications from local extension into surrounding bone and soft tissues.

CONTRAINDICATIONS

A herpetic whitlow is a herpes simplex virus infection of the distal phalanx that can be confused with an early paronychia or felon.^{13,18} The presence of multiple clear vesicles that coalesce suggests a herpetic whitlow. The herpetic whitlow is a nonsurgical and self-limited infection. Treatment consists of a dry dressing to the affected finger to prevent autoinoculation and transmission of the infection, oral antiviral agents, and analgesics. Incision and drainage is not recommended as it will prolong the recovery and may lead to secondary

FIGURE 132-1. Paronychia of the middle finger. (Used from Chris Craig at www.commonswikimedia.org.)

bacterial infection.¹⁹ A chronic paronychia should be referred to a Hand Surgeon or Dermatologist for treatment.²⁰

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- #11 scalpel blade or an 18 gauge needle
- Local anesthetic solution without epinephrine
- 18 and 27 gauge needles
- 5 to 10 mL syringe
- Ethyl chloride spray
- Forceps
- Mosquito hemostat
- Ribbon gauze packing, ½ inch wide
- Petrolatum gauze, ½ inch wide
- Scissors
- 4×4 gauze squares
- 18 gauge angiocatheter
- 20 mL syringe
- Sterile saline
- Adhesive tape

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Include in the informed consent any anesthetic technique used in the procedure. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Prepare the patient. Assess and update the patient's tetanus immune status if indicated. Place the patient on a gurney with the extremity on a bedside procedure table in a well-lit room. Soak the digit in warm water for 5 minutes to soften the skin. Perform a digital nerve block (Chapter 130) if the patient is apprehensive, has significant tenderness, or if it is not a simple paronychia or eponychia. Yellow or white overlying tissue may indicate that local sensory nerves have infarcted which makes anesthesia unnecessary.¹² Alternatively, apply ethyl chloride spray to the area until the skin turns frosty and pale (Chapter 154). Apply povidone iodine or chlorhexidine solution circumferentially to the digit and allow it to dry. The digit can be secured to a sterile tongue depressor for better control, especially in uncooperative children.

TECHNIQUES

SIMPLE PARONYCHIA OR EPONYCHIA

There is no need for a skin incision in an uncomplicated paronychia or eponychia. Simply lifting the eponychium off the nail plate at the point of maximal tenderness and/or fluctuance is usually curative. Slide the tip of a #11 scalpel blade or an 18 gauge needle under the paronychia, or eponychia, at the site of maximal fluctuance (**Figure 132-3**). Advance the scalpel blade to lift the soft tissue from the nail plate until there is an efflux of purulent fluid (**Figure 132-4A**). Apply digital pressure to the area to express the pus. Gently place a hemostat under the soft tissue to break any loculations (**Figure 132-4B**). Irrigate the pocket with an angiocatheter on a syringe containing sterile saline.

FIGURE 132-3. Drainage of a simple paronychia or eponychia. The eponychial fold is elevated from the nail plate with a #11 scalpel blade. Note that the blade is parallel to the nail plate, thereby avoiding injury to the nail matrix and not incising the skin.

Packing a paronychia is controversial. Place a small piece of ribbon gauze or petrolatum gauze under the elevated soft tissue (**Figure 132-4C**). Apply an antibiotic ointment (**Figure 132-4D**) followed by a simple dressing or bandage (**Figure 132-4E**). Oral antibiotics are not recommended for an uncomplicated paronychia or eponychia.²¹

PARONYCHIA WITH EXTENSION UNDER THE LATERAL NAIL PLATE

A more extensive incision and drainage is required when pus accumulates laterally and beneath the nail plate as a subungual abscess. Remove the lateral nail plate (Chapter 218) to allow adequate drainage (**Figure 132-5A**). Use scissors to cut the nail plate longitudinally. **Aim the point of the scissors upward and against the undersurface of the nail plate to prevent injuring the nail bed.** Remove the lateral nail plate with a hemostat. A small (i.e., 2 to 3 mm) incision may be required in the corner of the nail fold to remove the nail plate (**Figure 132-5A**). This will result in the egress of pus. Irrigate the area with saline. Insert a small piece of petrolatum gauze under the nail fold (**Figure 132-5B**). This will prevent the nail fold from fusing to the nail bed.

PARONYCHIA WITH EXTENSION UNDER THE PROXIMAL NAIL PLATE

A paronychia with extension under the proximal nail plate forming a subungual abscess requires removal of a portion of the proximal nail plate (**Figure 132-6**). Make two 3 to 4 mm long incisions at the corners of the nail folds to access the proximal edge of the nail plate (**Figure 132-6A**). Alternatively, bluntly raise the eponychium taking care not to damage the nail matrix.²² Cut the proximal one-third of the nail plate with scissors (**Figure 132-6B**). **Aim the point of the scissors upward and against the undersurface of the nail plate to prevent injuring the nail bed.** Grasp and remove the proximal segment of the nail plate with a hemostat. This will result in the egress of pus. Irrigate the area with saline. Insert a piece of petrolatum gauze under the nail fold to prevent it from fusing to the nail bed (**Figure 132-6C**).

Removal of the entire nail is rarely necessary except in the case of an extensive subungual abscess. An alternative to nail removal is trephination (Chapter 129) with a heated paper clip, a heat pen, or a microcautery unit.²² A large opening or multiple holes are required with this technique to eliminate the pus.

CHRONIC PARONYCHIA

Chronic paronychia result from inflammation secondary to prolonged exposure to finger biting, finger sucking, chemical irritants, cuticle trimming, moisture, a neoplasm, or psoriatic conditions.^{20,22,23}

**A****B****C****D****E**

FIGURE 132-4. Management of a paronychia. **A.** The skin fold is elevated with a #11 blade. **B.** A hemostat is inserted to break loculations. **C.** The paronychia is packed. **D.** Antibiotic ointment is applied. **E.** A dressing has been applied. (Used with permission from reference 5.)

FIGURE 132-5. Removal of the lateral nail plate is required when pus extends laterally below the nail plate. **A.** The dotted line over the nail represents the incision required to remove the nail plate. An additional incision may be required on the eponychium. **B.** The lateral portion of the nail plate has been removed and petrolatum gauze packing has been inserted to keep the nail fold elevated from the nail bed.

C. albicans has long been implicated in the pathogenesis. Studies suggest that chronic paronychia may not result from a primary mycotic infection but rather secondary colonization. Patients with diabetes or immunosuppression are more susceptible. Excessive hand washing is the likely culprit in occupational exposures of dish washers and health care workers. Treatment is likely not definitive in the Emergency Department. It is much more difficult to treat and eradicate than an acute infection. Removal of the causal irritant and topical steroids are first-line therapies. Favorable outcomes have been shown using topical steroids versus systemic antifungals.^{11,13} Patients who are not responsive to common interventions must be evaluated for a malignancy.

Definitive treatment for refractory chronic paronychia is eponychial marsupialization. This involves removal of a crescent-shaped piece of skin proximal to the nail fold and parallel to the eponychium. Complete or partial nail removal may be necessary if nail ridging is present.²⁴ A chronic paronychia may be confused with another condition that looks similar and mimics a chronic paronychia such as cysts, foreign body reactions, malignancies, psoriasis, and verrucae.^{23,25} Refer all chronic paronychia to a Hand Surgeon due to the higher rate of recurrence, the complexity in management, and where follow-up care can be more consistent.

AFTERCARE

Immobilize and elevate the digit. Instruct the patient to avoid nail biting or sucking. Any discomfort can be treated with acetaminophen or nonsteroidal anti-inflammatory medications. Follow-up care in 24 hours is important as complications can occur despite proper Emergency Department management. Packing of a simple paronychia should be removed in 24 hours. Warm soaks can begin immediately if packing is not placed. Delay warm soaks until the packing is removed in 24 hours. **There is no evidence that oral**

FIGURE 132-6. Removal of the proximal nail plate is required when pus extends proximally below the nail plate. **A.** Two incisions are required through the eponychium, represented by dotted lines. **B.** The dotted line over the nail plate represents the incision required to remove the nail plate. **C.** The proximal portion of the nail plate has been removed and petrolatum gauze packing has been inserted to keep the nail fold elevated from the nail bed.

antibiotics improve outcome after the incision and drainage of a simple and uncomplicated paronychia.²¹ Oral antibiotics are not necessary unless the nail bed is involved, there is apparent cellulitis of the surrounding tissue, or there are systemic signs of infection such as lymphangitis and fever.²⁶ Patients should return to the Emergency Department if they develop a fever, reaccumulation of pus, redness extending up the finger and hand, or increased tenderness to the digit.

Most simple paronychias resolve within a few days. If they persist longer or recur, consult a Hand Surgeon for more aggressive management (e.g., eponychial marsupialization and nail plate removal).

Paronychia or eponychia that extend under the nail plate require follow-up in 24 hours. The packing must be maintained between the nail fold and the nail bed for at least 5 to 7 days. **The nail fold will fuse to the nail bed if the packing is removed too soon and a new nail plate will not form.** These infections require a 5 to 7 day course of oral antistaphylococcal antibiotics. Nonsteroidal anti-inflammatory medications supplemented with occasional narcotic analgesics will provide adequate pain control for these patients.

COMPLICATIONS

Complications occur in even a properly drained paronychia (e.g., a felon, osteomyelitis of the distal phalanx, or a tenosynovitis). Superinfection with *C. albicans* or other fungi can also occur. These complications can be due to the paronychia itself or result from an inadequate incision and drainage procedure.

Complications from the incision and drainage procedure are rare if it is properly performed. Care must be taken if the lateral or proximal nail plate is removed to avoid damaging the underlying matrix so that a nail deformity does not result. Fusion of the nail fold to the nail bed will result in a new nail not being formed. Inadequate drainage can result in the infection spreading to adjacent bone and soft tissues. Incision of the skin instead of elevating it off the nail plate can result in prolonged healing.

SUMMARY

A paronychia is one of the most common hand infections. The treatment depends on the extent and location of the infection. The incision and drainage procedure is quick, simple, and easy to perform. Simple paronychias require elevation of the nail fold with no incision. A more extensive incision and drainage is required along with nail excision when pus accumulates below the nail plate. Follow-up is critical as complications may occur, even when the Emergency Department treatment is optimal.

Felon Incision and Drainage

Lisa R. Palivos and Sonali Gandhi

INTRODUCTION

A felon is a subcutaneous infection or abscess in the pulp space on the palmar aspect of the fingertip (**Figure 133-1**). It is usually caused by penetrating trauma, an abrasion, spread from adjacent tissues (e.g., eponychium, osteomyelitis, or paronychia), or a minor cut that leads to the invasion of bacteria.¹ A felon can develop in the presence of a foreign body (e.g., wood splinter or thorn).² It can be iatrogenic from multiple fingersticks for blood glucose measurement.^{3,4} The offending organism is usually *Staphylococcus aureus*.⁵ Mixed infections and gram-negative infections may occur in the immunocompromised patient. A felon can less commonly occur on the toes. The information in this chapter can be applied to a felon of the finger or the toe.

Felons initially present with a gradual onset of pain and erythema of the distal volar finger consistent with symptoms of cellulitis.¹ Intense throbbing pain, warmth, and swelling develop with the formation of an abscess as the infection progresses. **The definitive management for a felon is incision and drainage.** There are multiple techniques to incise and drain a felon. The patient requires digital elevation, immobilization, oral antistaphylococcal antibiotics, oral analgesics, and close follow-up to prevent complications following the incision and drainage.⁶⁻¹⁰

FIGURE 133-1. An example of a felon. (Used with permission from Knoop KJ, et al: *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2016. Photo contributor: Daniel L. Savitt, MD.)

FIGURE 133-2. Midsagittal section demonstrating the anatomy of the distal finger.

ANATOMY AND PATHOPHYSIOLOGY

The distal finger consists of a closed compartment that is bound by the nail plate dorsally, the skin ventrally and distally, and the flexion crease proximally (**Figure 133-2**). The fingertip pulp region is divided by 15 to 20 vertical fibrous septa.¹¹ These septa extend from the volar surface of the fat pad to the periosteum of the distal phalanx. They divide and compartmentalize the pulp area. An abscess in this enclosed space is confined by the septa which limits the proximal spread of an infection.¹² The septa inhibit the abscess from reaching the surface and inhibit drainage after the incision and drainage procedure. Blood is supplied by branches of the digital arteries that run parallel and lateral to the phalanx and terminate in the pulp region. The terminal branches of the digital nerves lie palmar and superficial to the arteries. The flexor digitorum profundus tendon inserts on the volar surface of the proximal distal phalanx.

INDICATIONS

All felons that are fluctuant should be incised and drained. Volar digital pads that are tense, tender, painful, and suspected of containing a felon should be evaluated for incision and drainage regardless if fluctuance is palpated or not.

CONTRAINDICATIONS

Felons that are not yet fluctuant, as in an early infection, may be treated with warm soaks, elevation, oral antibiotics, and follow-up in 24 hours.^{9,10} A herpetic whitlow can sometimes be confused with a felon.^{5,13} A herpetic whitlow can be clinically distinguished by the presence of multiple vesicles and a history of recurrence or simultaneous lesions (e.g., genital or oral). Treatment of a herpetic whitlow is nonsurgical and consists of a protective dry dressing, oral antiviral agents, and analgesics. Incision and drainage of a herpetic whitlow may spread the virus and predispose the patient to secondary bacterial infection.¹³

Consult a Hand Surgeon for complicated felons. This includes a felon that is associated with lymphangitis, osteomyelitis, a flexor tenosynovitis, an infection that has spread proximal to the distal

interphalangeal joint, or if the patient is immunocompromised. These patients require hospital admission, intravenous antibiotics, and possible incision and drainage in the Operating Room.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- #11 scalpel blade on a handle
- Local anesthetic solution without epinephrine
- 18 and 27 gauge needles
- 5 or 10 mL syringe
- 20 mL syringe
- Ethyl chloride spray
- Sterile saline
- 18 gauge angiocatheter
- Mosquito hemostat
- Ribbon gauze, ½ inch wide
- Bandage material
- Digital splint (e.g., plaster, preformed, or tongue depressor)
- Sling
- Digital tourniquet, optional
- Aerobic and anaerobic culture bottles, optional

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. Assess and update the patient's tetanus immune status if indicated.

Some physicians prefer to obtain anteroposterior and lateral radiographs of the digit to rule out an osteomyelitis or foreign body prior to performing the procedure. A positive radiograph for osteomyelitis will alter the time course for antibiotic therapy and require follow-up with a Hand Surgeon.

Place the patient on a gurney with the extremity on a bedside procedure table in a well-lit room. Soak the digit in warm water for 5 minutes to soften the skin. Perform a digital nerve block (Chapter 156) if the patient is apprehensive, has significant tenderness, or if it is not a simple felon. Alternatively, apply ethyl chloride topical spray (Chapter 154) to the area until the skin turns frosty and pale. Apply povidone iodine or chlorhexidine solution circumferentially to the digit and allow it to dry. Apply sterile drapes to delineate a sterile field. The digit can be secured to a sterile tongue depressor for better control, especially in uncooperative children. The application of a digital tourniquet (Chapter 129) to create a bloodless field is optional.

TECHNIQUES

Multiple incisions can be employed. Make an incision in the area of greatest fluctuance or tenderness with a #11 scalpel blade.⁶⁻⁹ Make a longitudinal incision if the maximal tenderness is in the center of the pulp of the distal fingertip (**Figure 133-3A**).^{1,5} **The incision should not come within 4 mm of or cross the crease of the distal interphalangeal joint as this can lead to injury of the flexor digitorum longus tendon or the joint, flexor tenosynovitis, and flexion contractures.**¹⁰ Make the incision along the lateral surface of

FIGURE 133-3. Recommended incisions for the incision and drainage of a felon. A felon should be incised and drained in the area of maximal fluctuance. **A.** The longitudinal fat pad incision over the area of maximum fluctuance. **B.** The unilateral longitudinal incision is high, lateral, and just below the level of the nail.

the finger if the felon has maximal tenderness on the radial or ulnar aspect of the finger (**Figure 133-3B**).¹ Purulent and/or bloody pink fluid will exit from the incision. Consider obtaining aerobic and anaerobic cultures of the purulent material. Bluntly and gently dissect the loculations with a mosquito hemostat. Irrigate the wound with an 18 gauge angiocatheter on a 5 or 10 mL syringe containing sterile saline. Place a piece of ribbon gauze into the wound. Apply a dry bulky dressing.

ALTERNATIVE TECHNIQUES

Alternative incisions have been advocated but are not recommended because they have higher complication rates (**Figure 133-4**).^{1,5} These incisions can result in neurovascular injury, painful scars, and altered fingertip sensation. The hockey stick incision can result in digital nerve injury and produce numbness to the fingertip (**Figure 133-4A**).⁸ The through-and-through or bilateral longitudinal incision can result in bilateral digital nerve injury and complete anesthesia of the fingertip (**Figure 133-4B**).⁹ The transverse palmar incision may transect the digital neurovascular bundles (**Figure 133-4C**). The fishmouth or horseshoe incision is very extensive, can take a long time to heal, and produces a large scar and an unstable pulp (**Figure 133-4D**).⁸

AFTERCARE

Splint the involved digit. Provide the patient a sling to keep the hand elevated. The incidence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) skin and soft tissue infections presenting

FIGURE 133-4. Incisions not recommended for the drainage of a felon. **A.** The hockey stick incision. **B.** The through-and-through or bilateral longitudinal incision. **C.** The transverse palmar incision. **D.** The fishmouth incision.

to the Emergency Department are increasing.^{1,4} An oral antibiotic effective against CA-MRSA is recommended.^{1,4,14,15} Sulfamethoxazole-trimethoprim, doxycycline, and clindamycin are appropriate choices for a 7 to 10 day course depending on local resistance patterns. Nonsteroidal anti-inflammatory medications supplemented with narcotic analgesics will control any postprocedural pain. Instruct the patient to soak the digit in warm water several times a day to speed healing. Patients should immediately return to the Emergency Department if they experience fever, increased pain, difficulty using the finger, redness of the finger or hand or arm, or a discharge from the wound.

The patient should be reevaluated in 24 to 48 hours for removal of the gauze and inspection of the digit. Remove the gauze during the follow-up visit. Perform a digital or metacarpal block for patient comfort. Irrigate the wound with sterile saline and break up any further loculations, if needed. Replace the gauze for another 24 to 48 hours if there is continued drainage.

COMPLICATIONS

Untreated or mistreated felons may cause skin necrosis, osteitis or osteomyelitis of the distal phalanx, septic arthritis of the distal interphalangeal joint, extension of the infection into the palm and adjacent fingers, suppurative tenosynovitis, and lymphangitis.¹⁶ Flexor tenosynovitis can occur if the incision is extended too far proximally and too deep. Improperly placed incisions can result in injury to the flexor digitorum profundus tendon or the distal interphalangeal joint, mobility of the pad of the finger, neurologic compromise, and/or vascular compromise. The lack of improvement within 24 to 48 hours requires consultation with a Hand Surgeon.

SUMMARY

Felons require incision and drainage. The procedure is quick, simple, and easy to perform. The incision should be made at the point of maximal fluctuance while avoiding injury to the digital arteries, digital nerves, the flexor digitorum profundus tendon, and the distal interphalangeal joint. Close follow-up is mandatory to prevent any complications. Consult a Hand Surgeon for any complications associated with the felon.

Pilonidal Abscess or Cyst Incision and Drainage

Carolyn Chooljian

INTRODUCTION

Controversy surrounds pilonidal disease, from who first described it, to the etiology, and how to manage it surgically. Some believe that pilonidal disease was first described in 1880 by Hodges.¹ However, others say it was first described in 1833 by Mayo.² Hodges used the term “pilonidal sinus” to describe a chronic infection that contained hair and was usually found between the buttocks. The word “pilonidal” comes from “pilus” or hair and “nidus” or nest. It literally means “nest of hair.” The condition did not receive much attention until it became a significant problem in the armed services around the time of World War II. In 1940, in the United States Navy, the number of sick days caused by pilonidal disease and its complications exceeded those of either syphilis or hernias.³ This condition was coined as “jeep disease” by Buie in 1944 because of the high occurrence rate in those who drove or were frequent passengers in military vehicles.⁴ There is an increased prevalence in drivers and others with occupations requiring long periods of sitting.⁵⁻⁷

Pilonidal sinus disease primarily affects Caucasian males. Blacks are infrequently affected and the condition is rare in Asians and Indians. Males are affected three to four times more frequently than females. The affected females tend to be younger than males.⁸ The condition is prevalent from the onset of puberty to young adulthood and is rare after the age of 40. The peak age of incidence is 21 years. The increased incidence in adolescents and young adults is attributed to hormonal effects of increased hair on the torso, increased activity of sebaceous and sweat glands, fat deposition on the buttocks, and deepening of the gluteal cleft. Other risk factors may include hirsutism, obesity, and poor personal hygiene. Repeated trauma to the area may also contribute to the formation of pilonidal disease. There is an increased prevalence in drivers and others with occupations requiring long periods of sitting.^{5,6}

Patients with pilonidal sinus disease may present with three different clinical pictures: asymptomatic disease, an acute abscess, or chronic disease. Asymptomatic disease patients have a painless sinus pit at the top of the natal cleft. Patients with chronic disease may have mild discomfort and a chronically draining sinus in the upper gluteal region. Approximately half of patients with symptomatic pilonidal disease will present acutely with severe pain and swelling that is indicative of a pilonidal abscess that necessitates incision and drainage (**Figure 134-1**).^{9,10} Inspection will reveal one or more midline sinus tract openings, often with protruding tufts of hair. The area will be tender, erythematous, and indurated when an abscess is present. Fluctuance and swelling may not be readily appreciated. The sinuses may be quite extensive depending upon the chronicity of the disease process prior to presentation. Patients with chronic disease may have mild discomfort and a chronically draining sinus in the upper gluteal region.

FIGURE 134-1. A pilonidal abscess. (Used with permission from Knoop KJ, et al: *The Atlas of Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2016. Photo contributor: Louis La Vopa, MD.)

ANATOMY AND PHYSIOLOGY

A pilonidal sinus consists of a characteristic midline opening, or series of openings, in the upper aspect of the gluteal cleft approximately 4 to 5 cm from the anus (**Figure 134-2**). The skin enters the sinus giving the opening a smooth edge. This primary tract leads into a subcutaneous cavity that contains granulation tissue and often a nest of hairs (**Figure 134-3**). The hairs may be seen projecting through the skin opening. Many sinuses have lateral or secondary openings (i.e., fistulas) extending from the pilonidal abscess (**Figure 134-3**).

Loose hairs from the adjacent gluteal region are thought to form a bristly tuft and penetrate into the skin, perhaps in an area of skin irregularity. This process may be aided by pressure on the region in persons with occupations that require long hours of driving or sitting. The hairs may also be pulled in by a suction effect between the moving buttocks. The hair penetrates the skin and causes a foreign body reaction and secondary inflammation with the potential for infection and abscess formation. The sinuses spread cranially and laterally. They rarely approach the anus and generally remain superficial to the presacral fascia.¹⁰⁻¹²

There have been various opinions as to the etiology of the condition since the first description of the disease. In the first half of the twentieth century, it was generally attributed to a congenital lesion. Some authors believed that the pilonidal sinus originated from a

FIGURE 134-2. Pilonidal sinuses occur in the midline, approximately 4 to 5 cm above the anus and in the natal cleft.

FIGURE 134-3. Cross-section through a pilonidal abscess and sinus. A primary tract and skin pit lead to the subcutaneous abscess. There may be secondary or lateral openings (fistulas).

remnant of the medullary canal that subsequently became infected. However, pilonidal disease can form in other areas of the body that lack hair, as some barbers have experienced in interdigital spaces.^{11,13} Currently, it is widely accepted that pilonidal disease is acquired.¹⁴ Some of the contributing factors to this belief are the rate of recurrence after excision, occurrence at other sites than the gluteal cleft, and the frequency seen among certain populations (e.g., barbers, armed forces).^{11,13}

INDICATIONS

Incision and drainage is indicated whenever a patient presents with a pilonidal abscess.¹⁵ Antibiotics alone are ineffective in treating a pilonidal abscess, although they are indicated when cellulitis is present.^{16,17} Rarely, systemic signs and symptoms may ensue. There are reported cases of necrotizing fasciitis from neglected pilonidal sinus disease. Thus it is preferable to treat pilonidal abscesses expeditiously with an incision and drainage procedure.

CONTRAINDICATIONS

Patients who are asymptomatic do not require an incision and drainage and can be referred to a Surgeon for removal. Most pilonidal abscesses may be drained in the Emergency Department. Patients with fever, systemic signs and symptoms, and/or toxicity should be admitted to the hospital for parenteral antibiotics, incision and drainage, and observation. This is particularly true if the patient has diabetes or is immunocompromised. Consult a Surgeon

to manage these patients. Extensive abscesses should be incised and drained in the Operating Room under general anesthesia. The procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.

EQUIPMENT

- Gown, face mask, and gloves
- Benzoin solution
- Povidone iodine or chlorhexidine solution
- Skin razor
- 10 mL syringe
- 25 or 27 gauge needle, 2 inches long
- Local anesthetic solution with epinephrine, lidocaine or bupivacaine
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Curved hemostat
- 4×4 gauze squares
- Ribbon gauze, plain or iodoform
- Adhesive tape

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedure care should be explained as well. Document the discussion of the risks and benefits of the procedure. Obtain a signed informed consent for the procedure.

The best visualization of the sacral region, particularly in obese patients, occurs with the use of a proctoscopic examination table, if available (**Figure 134-4A**). Place the patient prone on a gurney or on the proctoscopy table. Alternatively, place the patient in the lateral knee-chest position to expose the affected area (**Figure 134-4B**). Apply benzoin solution to the buttocks and allow it to dry. Apply adhesive tape to the buttocks and tape them open (**Figure 134-5**). Clean any dirt and debris from the skin overlying the abscess or

FIGURE 134-4. Patient placement. **A.** Prone on a proctoscopy table. The patient may also be placed prone on a gurney. **B.** The lateral knee-chest position.

FIGURE 134-5. Exposure of the abscess.

cyst. Apply povidone iodine or chlorhexidine solution and allow it to dry. Shave the surrounding area, if the patient is hirsute, to aid in the application of the dressing after the procedure. Some authors advocate shaving the sacral region to prevent recurrence as well, although this has not been proven to be effective. A gown, face mask, and nonsterile gloves are recommended to be worn for this procedure.

ANESTHESIA

Local anesthesia should be administered, recognizing that it is often difficult to obtain complete anesthesia by direct infiltration of an abscess.¹⁸ Local anesthetics are weak acids and are less effective in the acidic environment of an abscess. The skin over the abscess cavity usually becomes insensate, but anesthesia of the abscess cavity itself is not possible. The pain caused by injection of the local anesthetic solution is related to the rate that it is injected and the force necessary to inject it.

Inject the local anesthetic solution slowly through a small-bore needle (25 or 27 gauge) as the needle is withdrawn through the dermis. The needle bore will create a passage through the subcutaneous tissue as it is inserted that enables the local anesthetic solution to be infiltrated slowly and with less discomfort. Hold the syringe horizontal in reference to the skin surface. Inject 3 to 4 mL of local anesthetic solution intradermally over the dome of the abscess (**Figure 134-6**). The skin will blanch if the injection is given properly. **Do not inject the local anesthetic solution into the abscess cavity.** The increased pressure within the cavity will cause more discomfort to the patient and may cause the local anesthetic

FIGURE 134-6. Subcutaneous infiltration of local anesthetic solution. The needle and syringe are held parallel to the skin. The needle is inserted into the subcutaneous tissue overlying the pilonidal abscess. Infiltrate the local anesthetic solution as the needle is withdrawn. The skin should blanch (shaded area) if injected properly.

FIGURE 134-7. Field block anesthesia for a pilonidal abscess. **A.** Local anesthetic solution is infiltrated subcutaneously on all four sides of the abscess. **B.** The local anesthetic solution is infiltrated deep to the abscess cavity in a fan-like pattern.

solution or the abscess contents to be forcefully expelled if there is an opening in the skin.

Additional anesthesia is accomplished by performing a field block (**Figure 134-7**).¹⁹ Inject local anesthetic solution subcutaneously around the periphery of the abscess (**Figure 134-7A**). Inject local anesthetic solution deep to the abscess in a fan-like pattern (**Figure 134-7B**).

Systemic analgesia (i.e., procedural sedation and analgesia, Chapter 159) may be required since it is quite difficult to obtain adequate anesthesia of an abscess locally.¹⁸ Patient-administered nitrous oxide (Chapter 158), with or without supplemental narcotic analgesics, is an alternative to procedural sedation. Obtain an additional signed informed consent for the procedural sedation or the nitrous oxide administration. **The procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained in the Emergency Department and pain limits the procedure.**

A novel technique was used to anesthetize the pilonidal abscess.¹⁸ It does not require multiple infiltrations of the abscess or surrounding tissues. It involves the needle aspiration of the abscess followed by injection of local anesthetic slowly, in a volume to replace the purulent material aspirated, into the abscess cavity to anesthetize the area before incision and drainage. More information is needed before this technique of anesthesia can be recommended.

TECHNIQUE

Incise the skin over the area of maximum fluctuance with a scalpel blade. A 10% recurrence rate after drainage of chronic abscesses through a vertical incision lateral to the midline has been reported.²⁰ This may be due to better healing of wounds that are off the midline. Thus, some authors and Colorectal Surgeons recommend that the incision for an acute abscess be off the midline if the abscess can be drained adequately through the incision (**Figure 134-8A**). Extend the incision the length of the abscess to allow for proper drainage. A full-thickness, thin ellipse of skin can be removed to prevent premature closure of the skin edges. Approximately 40% of pilonidal abscesses will be cured from simple incision and drainage alone.²¹ It is not necessary to perform more radical excision procedures in the Emergency Department.

It is important that loculations be lysed and the area thoroughly drained to minimize recurrence. Several methods can be used to lyse adhesions within the cavity. A gloved finger may be used to bluntly break up the adhesions. Hemostats can be inserted and

FIGURE 134-8. Incision and drainage of a pilonidal abscess. **A.** An incision is made lateral to the midline and overlying the abscess cavity. **B.** A hemostat with gauze clamped in the jaws is inserted into the abscess cavity and rotated to break loculations and remove debris.

spread within the abscess cavity. A useful technique employs a 4×4 gauze square clamped in a hemostat and swirled inside the abscess cavity to break adhesions and remove debris (**Figure 134-8B**). This technique aids in removing hair and the infected lining of the cyst. Irrigation of the abscess cavity with normal saline is left to the Emergency Physician's discretion but may not be necessary.²²

Loosely pack the cavity with ribbon gauze. Packing the cavity too tightly may cause ischemia to the surrounding tissue, delays healing, and is uncomfortable for the patient. The purpose of the packing is to keep the skin edges from adhering before the cavity closes. Cover the incision with a simple bandage composed of gauze and adhesive tape. A thick layer of absorbent gauze will soak up any continued drainage.

ALTERNATIVE TECHNIQUE

A loop (Chapter 131) can be used to drain the pilonidal abscess.²³ A similar technique has been used in China for more than 40 years.²³ They refer to this technique as suture-dragging.

AFTERCARE

Antibiotics are generally unnecessary to treat a simple abscess when there is no cellulitis surrounding the wound.^{5,6,16,17,24} No data could be found on the optimal duration of antibiotic treatment if the overlying skin is cellulitic. The conventional 7 to 10 day course of antibiotics is probably adequate. Patients with diabetes, patients with cardiac valve disease, those who have hardware in their body, or those who are immunocompromised and have a pilonidal abscess are at risk for infectious complications and it is advised that they be treated with oral antibiotics.^{15,16}

There is a disparity in the literature regarding the bacteriology of pilonidal abscesses. *Staphylococcus aureus* is the most commonly found bacteria, and surprisingly, *Escherichia coli* is rarely found.²⁵ A report in children recovered primarily anaerobes from pilonidal cysts.²⁶ *E. coli* was the most common aerobe cultured from this series. **In light of these conflicting results and in the event that antibiotics are deemed necessary, coverage for skin flora as well as aerobes and gram-negative organisms would be advised.** A combination of a first-generation cephalosporin or penicillinase-resistant penicillin along with metronidazole or clindamycin is recommended. **Keep in mind the ever increasing rates of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) infections.** Consider prescribing clindamycin, doxycycline, or trimethoprim-sulfamethoxazole if CA-MRSA is a potential pathogen.⁸

Instruct the patient to change the gauze dressing as often as necessary to keep the outside of the dressing dry. The patient should

return for follow-up in 48 hours for a wound check and removal of the packing. If the wound is large or there is not a clear open tract for continued drainage, reinsert new packing upon follow-up. Incisions that remain open do not require repacking. Advise the patient to have the packing changed every 24 to 48 hours depending upon the amount of drainage. Decrease the amount of packing each time to allow the wound to heal from the base outward. The patient should thoroughly wash the wound with soap and water in the shower or take a sitz bath each time the packing is removed. It is helpful to let the stream of shower water run inside the wound to aid in wound irrigation. After showering, the patient should dry the area thoroughly. Discontinue the packing once the wound is well granulated and there is no concern that the skin edges will adhere to each other. The patient must continue to clean the wound thoroughly every day until it is fully healed. Healing may take several weeks depending upon the size of the abscess cavity. Instruct the patient that they must return to the Emergency Department if they develop a fever, increased pain, or increased redness of the skin surrounding the abscess. Patients often have pain in the first 2 to 3 days after the incision and drainage. This can be controlled with nonsteroidal anti-inflammatory drugs and supplemented with occasional narcotic analgesics.

Inform the patient that incision and drainage in the acute care setting is not definitive treatment and that the condition may recur. Arrange for follow-up with a Surgeon who can provide wound care as well as definitive therapy if surgery is required. Definitive treatment of a chronic pilonidal abscess or sinus still remains controversial among Colorectal Surgeons. Options include de-roofing and curettage, excision with primary closure, wide excision with secondary closure, or marsupialization.^{2,22,27-33}

Educate the patient about their role in the prevention of a recurrence. Recurrence may be prevented with meticulous hygiene and periodic shaving or hair removal to the area.^{11,19,34,35} The application of phenol on follow-up has shown promise to prevent recurrence.³⁶⁻³⁸ Instruct the patient on the methods for meticulous hygiene in the area, even after the wound has healed. Repeated trauma to the area should be avoided. This includes exercises such as sit-ups and leg lifts and prolonged periods of sitting.

COMPLICATIONS

Pilonidal disease may return, even with radical and extensive surgical excision procedures. **Thus, recurrence is to be expected, and the patient should be alerted to this possibility.** Rarely, pilonidal lesions progress to necrotizing fasciitis. Proceed cautiously with patients who are diabetic or otherwise immunocompromised as they are at risk for widespread infections. Those with systemic signs and symptoms are best admitted for treatment. Necrotizing fasciitis is a surgical emergency and requires extensive operative debridement, systemic antibiotics, and intensive supportive care.

Alternative diagnoses should be considered when evaluating patients with pilonidal disease including hidradenitis suppurativa, furuncles, Crohn's disease, perianal fistula, and infections such as tuberculosis, syphilis, and actinomycosis.¹⁵ Rarely, a nonhealing pilonidal infection may be a pilonidal sinus malignancy.³⁹ Squamous cell carcinoma has been described to arise from chronic sinus tracts. This emphasizes the importance of follow-up for all patients with pilonidal sinus disease.

Other complications include infection and tissue injury. The incision and drainage procedure can result in a subsequent cellulitis, endocarditis, fasciitis, meningitis, myositis, sacrococcygeal osteomyelitis, or septicemia. The sharp and blunt dissection can injure underlying or adjacent structures including blood vessels, the coccyx, muscles, nerves, and tendons.

SUMMARY

Pilonidal disease is common in the young adult population and more prevalent in males. It is now widely accepted as being an acquired condition caused by hair that penetrates an irregular area of skin in the sacral area. Pits occur in the skin that in turn lead to cysts in the subcutaneous tissue. Patients may present with asymptomatic pits, chronically draining sinuses, or acute painful abscesses. No treatment is necessary for asymptomatic patients. Nontender sinuses may be referred for surgical treatment. Abscesses should be drained expeditiously under adequate analgesia and anesthesia. Antibiotics are not indicated unless the patient has surrounding cellulitis or is immunocompromised. Recurrences are common and patients must be referred for follow-up with a Surgeon who can provide wound care as well as surgical treatment for chronic cases.

Perianal Abscess Incision and Drainage

John Ramos and Deena Bengiamin

INTRODUCTION

Anorectal infections are common problems presenting to the Emergency Department. Understanding anorectal anatomy is essential to make a diagnosis, institute proper treatment, and anticipate complications. Failure to diagnose and treat an extensive abscess may be life threatening. Surgical consultation is imperative if the extent of an abscess is unclear.

Anorectal infections occur mostly in the third or fourth decade of life. Perianal abscesses (**Figure 135-1**) are two to three times more common in men than women.^{1,2} Male predominance is even more pronounced in the pediatric population.³ In one series, all patients under 2 years of age and 60% greater than 2 years were males.³ The increased incidence of perianal infection in males may be related to androgen conversion in the anal glands.⁴ Deep anal crypts are associated with perianal abscesses in infants.⁵

Abscesses may completely resolve after proper incision and drainage. Approximately 50% recur or develop a chronic epithelialized tract or fistula-in-ano. Abscesses and fistulas are different sequelae of the same process.⁶

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of the anatomy of the region is important to understand the pathophysiology of anorectal infections (**Figures 135-2 and 135-3**). Columnar epithelium transitions to squamous epithelium at the columns of Morgagni at the level of the dentate line. Semilunar folds of epithelium called anal valves connect the inferior borders of the anal columns. At the base of each anal valve is an anal crypt into which the ducts of the anal glands drain. The anal glands are

FIGURE 135-1. A perianal abscess. (Used with permission from Hornez E, et al: Surgical proctologic emergency in isolated sea-based environment: how is it performed in the French navy. *Mil Med* 2013; 178(4):e498-e502.)

positioned circumferentially in the anal canal and secrete mucus to aid in the evacuation of feces. The anal glands are in the space between the internal and external anal sphincter muscles. Most anorectal infections begin in this intersphincteric space due to blockage and resultant infection of the anal glands.⁷

The spread of an infection is determined by the anatomy of the anorectal region. There are five anatomic spaces into which an infection can spread (**Figure 135-4**).⁶ The perianal space is located at the area of the anal verge. The ischioanal space is continuous with the perianal space and extends from the levator ani muscle to the perineum. The submucosal space can be visualized with the use of anoscope. The intersphincteric space lies between the internal and external anal sphincter muscles. It connects inferiorly with the perianal space and superiorly with the rectal wall. The supralelevator

(i.e., pelvirectal) space is located superior to the levator ani muscle. It is bounded superiorly by the peritoneum, laterally by the pelvic wall, and medially by the rectum. The deep postanal space is located between the tip of the coccyx and the anus. It courses through the superficial external anal sphincter and the levator ani. The superficial postanal space lies posterior to the anal verge and is subcutaneous. The retrorectal space is high in the pelvis. It occupies the area between the distal rectum and the sacrum.

Most anorectal infections begin in the intersphincteric space. Natural barriers are broken down by the formation of an abscess and the infection can spread to contiguous spaces. Abscesses are classified by their location.⁸ Perianal abscesses are common and make up 60% of abscesses. Ischioanal abscesses occur less frequently at 22%, and supralelevator abscesses are the least common type at 9%. Bilateral involvement may occur when an infection spreads circumferentially via the deep postanal space and results in a horseshoe abscess.

Patients with anorectal abscesses present with buttock pain and swelling. There is purulent drainage at the abscess site if it spontaneously drains. Symptoms depend upon the location of the abscess. Patients with perianal infections have anal pain that increases with defecation or sitting. Pain associated with deeper infections may be atypical. Patients with supralelevator abscesses may have deep rectal pain, gluteal pain, dysuria, or other urinary symptoms.

Erythema, swelling, and fluctuance are often present on examination at the abscess site. The location of the swelling and fluctuance of a perianal abscess is at the anal verge. Ischioanal space infections track farther from the anus onto the buttock. Supralelevator and intersphincteric abscesses may have minimal or no external signs.⁹ **The diagnosis of perianal cellulitis is highly suspect. These patients have either an anorectal abscess or Fournier's gangrene until proven otherwise. Patients with gluteal pain and a small amount of erythema in the perianal area have a deep-seated abscess until proven otherwise.**

A digital rectal examination is necessary as intersphincteric, deep postanal, and submucosal abscesses may be palpated but often cannot be appreciated on external examination. **A superficial digital**

FIGURE 135-2. The anatomy of the anal canal.

FIGURE 135-3. The major structures of the anal canal.

examination of the anal canal alone is inadequate for detection of some abscesses. The gloved finger must extend into the rectum seeking tenderness and a mass. The digital rectal examination may fail to detect some deep abscesses due to patient discomfort.

FIGURE 135-4. The anorectal spaces. **A.** Coronal section through the pelvis. **B.** Sagittal section through the pelvis.

Obtain a computed tomography (CT) scan of the pelvis with rectal and intravenous contrast if unable to obtain an adequate examination due to pain or if a deep abscess is suspected.¹⁰

A fistula-in-ano represents the chronic phase of an unhealed perianal abscess. Fistulas may form due to persistent obstruction of the anal gland, inadequate drainage of a perirectal abscess, or rupture of a perianal abscess.¹¹ The tract eventually becomes epithelialized with glandular tissue. Fistulas may also form due to epithelialization by cells derived from the transitional zone of the anal canal and thus may be unrelated to persistent anal gland disease.¹² Patients with a fistula-in-ano will often give a history of a previous abscess. Developing a fistula-in-ano does not appear to be related to whether the abscess drained spontaneously or surgically.¹³ Patients may complain of chronic drainage from the site or subacute pain.

Physical examination of a fistula-in-ano reveals an external opening with scant drainage and visible surrounding granulation tissue. Digital rectal examination may reveal an indurated cord-like structure beneath the skin within the anal canal. The internal opening may be palpable along the dentate line. Pus may be expressed externally or from within the anus upon palpation of the fistulous tract.

The greater the distance from the anus that the external opening is located, the more complex is the fistulous tract. Goodsall's rule describes the likelihood of the location of fistulous tracts and the internal opening based upon the location of the external opening (**Figure 135-5**).¹⁴ Anterior external openings tend to communicate in a linear fashion with the internal opening in the anal canal. Fistulas with posterior external openings tend to communicate in a curvilinear fashion with the internal opening.

Not all perianal bumps are an abscess. An abscess must be distinguished from other diseases that affect the area. This includes actinomycosis, Crohn's disease, Fournier's gangrene, a furuncle, herpes simplex, hidradenitis suppurativa, human immunodeficiency virus (HIV)-related complications and diseases, malignancies, radiation fibrosis, sexually transmitted diseases, syphilis, and tuberculosis.¹⁵⁻¹⁸ Obtain a CT scan and consult a surgeon if unclear of the diagnosis.

FIGURE 135-5. Goodsall's rule.

Patients with multiple or recurrent fistulas require evaluation for Crohn's disease. This is particularly true if associated with chronic diarrhea or cramping, both of which suggest inflammatory bowel disease. Recurrent fistulas may be indicative of tuberculosis or a sexually transmitted disease (e.g., lymphogranuloma venereum). It is imperative that these patients be referred to a Surgeon who is experienced in managing anorectal disease.

INDICATIONS

Incision and drainage is the treatment for an anorectal abscess.^{15,18} Uncomplicated perianal abscesses and submucosal abscesses may be drained in the Emergency Department. Management of deeper or more extensive abscesses should be in consultation with a Surgeon. **Use caution in draining abscesses.** The ischiorectal space is quite large, particularly in the obese patient, and adequacy of drainage is not assured except under general anesthesia. It is not uncommon for an abscess to have a small erythematous and swollen area on the buttock overlying an extensive and deep abscess. Attempts at drainage in the Emergency Department may be inadequate.

Perianal disease is commonly encountered in the HIV-infected patient. Complication rates were noted to be high in the past and a hands-off approach was espoused. More recent data suggest that patients with a relatively preserved immune system may safely undergo standard surgical drainage. Small perianal abscesses may be drained in the Emergency Department. Consult a General or Colorectal Surgeon for patients with late-stage HIV disease. Infections are more likely to be extensive and anorectal sepsis is more common because these patients have poor wound healing.¹⁹

CONTRAINDICATIONS

Most small, uncomplicated perianal, and submucosal abscesses can be drained in the Emergency Department. **A General or Colorectal Surgeon should drain all other types of anorectal abscesses. Caution is urged when an abscess is on the buttock because it may manifest an ischiorectal abscess.** Patients with bleeding disorders, taking anticoagulants, or with thrombocytopenia should be managed by a Surgeon. Consult a Surgeon if the infection is extensive or if the extent of the abscess cannot be determined. Surgical consultation is also necessary for patients with purulent drainage from inside the anus. Internal findings may indicate that the patient has an intersphincteric or a supralelevator abscess, the full extent of which can be determined only under general anesthesia. The procedure should be conducted by a Surgeon under general anesthesia in the

Operating Room if adequate anesthesia cannot be obtained or pain limits the procedure in the Emergency Department.

Patients with fever or toxicity should be admitted to the hospital for parenteral antibiotics, incision and drainage in the Operating Room, and observation. **Anorectal infections occasionally progress to necrotizing fasciitis which is a true surgical emergency.** Physical examination findings in such cases may initially be minimal except for systemic signs or symptoms. Patients who are immunocompromised or with late-stage HIV infection should be referred to an experienced Surgeon due to the higher complication rate and increased risk of extensive infection.

Chronically draining fistulas without an acute infection should be referred to a General or Colorectal Surgeon for care. Patients with purulent drainage from the anus, even if there is no significant tenderness, should be examined under general anesthesia as they may still have an internal abscess along with a fistulous tract.

EQUIPMENT

- Gown, face mask, and gloves
- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 25 or 27 gauge needle, 2 inches long
- Local anesthetic solution with epinephrine
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Curved hemostat
- 4×4 gauze squares
- 10 to 16 French mushroom (de Pezzer) catheter (optional)
- Adhesive tape
- Feminine napkin (optional)
- Normal saline
- 18 gauge angiocatheter
- 20 mL syringe
- 2–0 nylon suture
- Needle driver
- Scissors

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure along with alternatives to the patient and/or their representative. The postprocedure care should be explained as well. Document the discussion of the risks and benefits of the procedure. Obtain an informed consent for the procedure. Wear a face mask, gown, and gloves for the entire procedure. The injection of local anesthetic solution can force abscess contents to shoot out. Incision of a tense abscess can also result in contamination.

The best visualization of the sacral region, particularly in obese patients, occurs with the use of a proctoscopic examination table (Figure 135-6A). Place the patient prone on a gurney or on the proctoscopy table. Alternatively, place the patient in the prone or lateral knee-chest position on a gurney or examination table to expose the affected area (Figure 135-6B). Apply benzoin solution to the buttocks and allow it to dry. Apply adhesive tape to the buttocks and tape them open (Figure 135-7). Clean any dirt, stool, and debris from the skin overlying the abscess or cyst. Apply povidone iodine or chlorhexidine solution and allow it to dry. Shave the surrounding area, if the patient is hirsute, to aid in the application of the dressing after the procedure.

FIGURE 135-6. Patient placement. **A.** Prone on a proctoscopy table. The patient may also be placed prone on a gurney. **B.** The lateral knee-chest position.

ANESTHESIA

Local anesthesia must be administered, recognizing that it is often difficult to obtain complete anesthesia by direct infiltration of an abscess. Local anesthetics are weak acids and are less effective in the acidic environment of an abscess. The skin over the abscess cavity usually becomes insensate, but anesthesia of the abscess cavity itself is not possible. The pain caused by injection of the local anesthetic solution is related to the rate that the anesthetic is injected and the force necessary to inject it. **Inject the local anesthetic solution slowly through a small-bore needle (e.g., 25 or 27 gauge) as it is withdrawn through the dermis.** The needle bore will create a passage through the subcutaneous tissue as it is inserted that enables the local anesthetic solution to be infiltrated slowly and with less discomfort.

Hold the syringe horizontal to the skin surface. Inject 3 to 4 mL of local anesthetic solution intradermally over the dome of the abscess (**Figure 135-8**). The skin will blanch if the injection is given properly. **Do not inject the local anesthetic solution into the abscess cavity.** The increased pressure within the cavity will cause more discomfort to the patient and may cause the solution to be forcefully expelled if there is an opening in the skin.

Additional anesthesia is accomplished by performing a field block (**Figure 135-9**). Inject local anesthetic solution subcutaneously around the periphery of the abscess (**Figure 135-9A**).²⁰ Inject

local anesthetic solution deep to the abscess in a fan-like pattern (**Figure 135-9B**).

Systemic analgesia in the form of procedural sedation (Chapter 159) is usually required since it is difficult to obtain adequate anesthesia of an abscess locally. Self-administered nitrous oxide (Chapter 158) with or without opioid supplementation is an alternative. Obtain an additional informed consent for the procedural sedation or nitrous oxide administration. **The procedure should be conducted by a Surgeon under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained or pain limits the procedure.**

TECHNIQUES

INCISION AND DRAINAGE OF PERIANAL ABSCESSES

Make a stab incision with a #11 scalpel blade in the skin overlying the area of fluctuance to decompress the abscess (**Figure 135-10**). **Make the incision as close to the anus as possible so that if a fistula forms, its size will be limited.** This maneuver will minimize the length of a fistulotomy in the future should it become necessary. Extend the incision with the #11 scalpel blade or a #15 scalpel blade in a full-thickness elliptical pattern along the length of the abscess cavity or the area of fluctuance (**Figure 135-11A**). Remove the ellipse of skin (**Figure 135-11B**). A full-thickness ellipse of skin is excised to prevent premature closure of the skin edges. Some prefer

FIGURE 135-7. Exposing the abscess.

FIGURE 135-8. Subcutaneous infiltration of local anesthetic solution. The needle and syringe are held parallel to the skin. The needle is inserted into the subcutaneous tissue overlying the abscess. Infiltrate the local anesthetic solution as the needle is withdrawn. The skin should blanch (shaded area) if injected properly.

FIGURE 135-9. Field block anesthesia. **A.** Local anesthetic solution is infiltrated subcutaneously on all four sides of the abscess. **B.** The local anesthetic solution is infiltrated deep to the abscess cavity in a fan-like pattern.

to make a cruciate incision over the abscess and excise the edges (**Figure 135-12**).⁶ These techniques delay cutaneous healing while the abscess is decompressing and allow it to drain freely without the need for packing.

FIGURE 135-10. The initial stab incision into the perirectal abscess. (Used with permission from Hornez E, et al: Surgical proctologic emergency in isolated sea-based environment: how is it performed in the French navy. *Mil Med* 2013; 178(4):e498-e502.)

FIGURE 135-11. Drainage of a perianal abscess. **A.** An elliptical incision is made in the skin. **B.** The ellipse of skin is removed to prevent premature closure of the skin edges.

A linear incision is acceptable but is not recommended for a perianal abscess. The body location and excessive skin often result in premature closure before the cavity has healed. A linear incision requires repeated packing at 24 to 48 hour intervals to prevent premature closure. The area is difficult to access by the patient to pack the cavity. The pain of repeated packing often results in noncompliance. It is also difficult for the patient to wash out the cavity in the shower or bathtub.

It is important that loculations be lysed and the area thoroughly drained to minimize recurrence. Several methods can be used to lyse adhesions within the abscess cavity. A gloved finger may be used to bluntly break up the adhesions. Hemostats can be inserted and spread within the cavity. A useful technique employs a gauze 4×4 square clamped in a hemostat and swirled inside the abscess cavity to break adhesions and remove debris. Irrigate the cavity with normal saline.

It is not necessary to pack an incised and drained perianal abscess that has been incised by removing a full-thickness skin ellipse or a cruciate incision. Consider temporarily packing the abscess cavity in the Emergency Department to control any hemorrhage. Remove the packing before discharging the patient and to reassess the need for further hemorrhage control. Cover the wound with a thick layer of absorbent gauze to soak up continued drainage. A feminine napkin may also be used to absorb drainage and obviates the need for taping the dressing in place.

CATHETER DRAINAGE OF PERIANAL ABSCESSES

Another method used to drain perianal abscesses, and preferred by some Colorectal Surgeons, is catheter drainage.¹⁵ The mushroom or de Pezzer catheter has a tunnel through a solid mushroom-shaped tip (**Figure 135-13A**).²¹ Make a stab incision with a #11 scalpel blade over the anal side of the area of fluctuance (**Figures 135-10 and 135-13B**). Lyse any adhesions and express the pus. Flush the abscess cavity with normal saline using an 18 gauge angiocatheter on a 20 mL syringe.

Insert a 10 to 16 French latex mushroom catheter using a hemostat to stretch the tip so that it will fit through the incision (**Figure 135-13C**). Place the tip of the hemostat through the hole in the mushroom catheter. Holding the hemostat with one hand,

FIGURE 135-12. Drainage of perianal abscess employing a cruciate incision. **A.** The cruciate incision is made over the abscess. **B.** Excision of the skin flap edges. **C.** The final appearance.

FIGURE 135-13. Catheter drainage of an abscess. **A.** The mushroom (de Pezzer) catheter. **B.** A stab incision is made over the area of maximal fluctuance. **C.** Place the tip of the hemostat through the side hole to stretch the tip of the catheter. Insert the stretched catheter through the stab incision. **D.** Remove the hemostat to expand the head of the catheter so that it remains within the abscess cavity. **E.** The catheter is cut so that it protrudes 2 to 3 cm from the skin incision.

use the other hand to pull on the tubing to stretch the mushroom tip and enable it to fit into the abscess cavity (**Figure 135-13C**). Insert the stretched mushroom tip into the abscess cavity (**Figure 135-13C**). Release the traction on the hemostat once the catheter tip is within the abscess cavity and the mushroom shape will be restored (**Figure 135-13D**). Remove the hemostat from the abscess cavity.

Suture the catheter in place. Place a single simple interrupted stitch using 2-0 nylon adjacent to the stab incision. Leave both ends long, tie the suture knots, and do not cut the suture. Pass the needle through the catheter as it exits the skin incision. Tie the needle end of the suture to the tail end of the suture to secure the catheter. Cut off the excess suture. Cut the catheter so that it protrudes only 2 to 3 cm from the incision (**Figure 135-13E**). Apply a dressing of gauze squares or a feminine napkin.

Many Colorectal Surgeons prefer the catheter method. Subsequent visits can assess the wound for the presence of a fistula without removing the catheter. Hydrogen peroxide can be infused through the catheter. Bubbles seen escaping from an opening within the anal canal are diagnostic for a fistula. Hydrogen peroxide is also used to produce an ultrasound interface that facilitates the definition of a fistulous tract and the internal opening.⁶ The smaller stab incision takes less time to heal than the larger incision and drainage wound.

SUBMUCOSAL ABSCESSSES

Most submucosal abscesses may be drained in the Emergency Department. The procedure requires the use of an anoscope (Chapter 88) to visualize the abscess. Make a superficial stab incision in the abscess with a #11 scalpel blade. Gently insert a hemostat and lyse any adhesions. Remove a small ellipse of the mucosa to allow the abscess to drain. Arrange follow-up with a Colorectal Surgeon within 24 hours.

AFTERCARE

The questions of bacterial cultures and antibiotic administration always come up in relation to these abscesses. Bacterial cultures are not helpful.²² Antibiotics are generally unnecessary to treat a simple abscess when there is no cellulitis surrounding the wound.^{15,23} No data could be found on the optimal duration of antibiotic treatment if the overlying skin is cellulitic. Antibiotic treatment should not delay surgery. The conventional 7 to 10 day course of antibiotics is likely adequate. There are minimal data in the literature regarding the treatment of patients with diabetes, patients with cardiac valve disease, those who have hardware in their body, or those who are immunocompromised with antibiotics for a perianal abscess.²⁴ These patients are at risk for infectious complications. It is advised that they be treated with antibiotics.²⁵ Bacteriology of anorectal abscesses is polymicrobial with coliforms and anaerobes predominating.^{18,26} Recommended antibiotics include an extended-spectrum β -lactam, a second- or third-generation cephalosporin with metronidazole or clindamycin, or a newer fluoroquinolone with metronidazole or clindamycin.

The patient may change the gauze dressing as often as necessary to keep the outside of the dressing dry. Instruct the patient to return for follow-up in 48 hours for removal of packing if placed and a wound check. The patient may begin sitz baths or showers 24 hours after the procedure. They should thoroughly clean the wound with soap and water at least once a day until the wound is fully healed. It is helpful to let the stream of shower water run inside the wound to aid in irrigation. Healing may take several weeks depending upon the size of the abscess. Additional measures to aid in healing and comfort include stool bulking agents and stool softeners. Pain can be controlled with nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesics.

Advise the patient that the condition is likely to recur. They must be referred to a General or Colorectal Surgeon who is experienced in the management of anorectal infections. Inform the patient that they may require an operation to prevent future recurrences. Instruct the patient to immediately return to the Emergency Department if they develop a fever, increased pain or redness to the area, or a foul smell to the discharge.

COMPLICATIONS

Perianal abscesses may recur or a fistula may form. Recurrence is more likely in children or if the patient has had abscesses in the same location in the past.²⁷ Anorectal infections progress to necrotizing fasciitis in less than 1% of patients.²⁸ Any systemic signs and symptoms require surgical consultation, hospital admission, parenteral antibiotics, and a drainage procedure.²⁹

Complications associated with the incision and drainage procedure are rare. A linear incision or too small of an incision can result in premature skin closure, incomplete healing of the cavity, and recurrence. Too large of an incision can result in delayed healing. An overly aggressive incision can damage adjacent structures. Postprocedural bleeding is rare.

SUMMARY

Anorectal infections are commonly seen in the Emergency Department. They are thought to be due to obstruction and subsequent infection of the anal glands that form an abscess. Small perianal abscesses and submucosal abscesses can safely be drained in the Emergency Department. A digital rectal examination may aid in determining the extent of an abscess. A General or Colorectal Surgeon should manage patients with fever, signs of toxicity, or

evidence of a deep or extensive infection beyond the perianal area or patients who are immunocompromised. Be alert that abscesses with maximum fluctuance on the buttock are more likely to have ischiorectal extension, are more complex, and are greater in size. Perianal abscesses must be drained expeditiously to prevent their spread. Approximately 50% of anorectal abscesses will develop a fistulous tract. Patients require referral for follow-up with a General or Colorectal Surgeon who can provide wound care as well as manage chronic cases.

Sebaceous Cyst Incision and Drainage

Carlos J. Roldan

INTRODUCTION

Sebaceous cysts are common, present with a very benign evolution, may be located anywhere on the body, and frequently become infected. They are most commonly found on the face, neck, and trunk. Sebaceous cysts are usually asymptomatic unless they become infected, cause compression, or cause a deformity over sensitive areas of the body (**Figure 136-1**). The Emergency Physician must be acquainted with treating infected sebaceous cysts, particularly if they are located on cosmetically important areas such as the face.

ANATOMY AND PATHOPHYSIOLOGY

Sebaceous cysts are the result of obstruction of sebaceous gland ducts. They are freely mobile, slow growing, round shaped, painless, and located in the subcutaneous tissues.¹ The cysts are made of a thin white capsule filled with a thick, cheesy, and keratinous material. Their size is variable and ranges from less than a quarter of an inch to more than 2 inches. These keratin-containing lesions are usually seen in young and middle-aged adults in relation to a pilosebaceous follicle.² Sebaceous cysts may be present for many years before infection occurs. Physical examination often reveals a subcutaneous mass that is fluctuant and tender (**Figure 136-1**). The overlying skin may appear normal or erythematous.

The initial treatment of choice of an infected sebaceous cyst is incision and drainage. The sebaceous material is too thick to allow for spontaneous drainage and it must be expressed. **The sebaceous cyst will likely recur unless the capsule of the cyst is removed.** Patients may have the initial incision and drainage performed in the Emergency Department with follow-up at some later date to remove the cyst capsule. Alternatively, the cyst capsule may be removed at the time of the initial incision and drainage (**Figure 136-2**).

Ultrasound is a useful tool for the diagnosis of a sebaceous cyst.³⁻⁵ It allows for the differential between it and its mimics (e.g., cutaneous masses, hernia, lipoma, lymph node, subcutaneous malignancies, or a vascular abnormality). It can be difficult to distinguish between a sebaceous cyst and another entity. A sebaceous cyst may appear as a small, well-defined, and superficial mass. The inside appearance can vary with the contents.

FIGURE 136-1. An example of an infected sebaceous cyst located on the posterior neck. (Used from Steven Fruitsmack, www.commonswikimedia.org.)

FIGURE 136-2. The removed sebaceous cyst. Note that it is enclosed in a connective tissue capsule. (Used from Steven Fruitsmack, www.commonswikimedia.org.)

INDICATIONS

Incision and drainage in the Emergency Department is indicated whenever a patient presents with a tender sebaceous cyst consistent with an abscess. The procedure will relieve the patient's pain. Antibiotics without drainage are ineffective in treating abscesses.⁶ The vast majority of infected sebaceous cysts may be drained in the Emergency Department, Urgent Care setting, clinic, or office setting. A noninfected sebaceous cyst may be removed electively and for cosmetic purposes in the clinic or office setting by a Primary Care Provider or a Surgeon (**Figure 136-2**).

CONTRAINDICATIONS

There are no absolute contraindications to the incision and drainage or removal of an infected sebaceous cyst. Caution is advised in patients with bleeding disorders, taking anticoagulants, or with thrombocytopenia. Incision and drainage is preferred if the overlying skin is cellulitic. The capsule can be removed at a later time. Manage patients with extremely large abscesses, those with cosmetic concerns, or those in which adequate anesthesia is not possible in the Operating Room by a General Surgeon or Plastic Surgeon. The procedure is to be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure. Refer patients with noninfected sebaceous cysts to their Primary Care Physician, a General Surgeon, or a Plastic Surgeon for removal.

EQUIPMENT

- Gown, face mask, and gloves
- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 25 or 27 gauge needle, 2 inches long
- Local anesthetic solution, with or without epinephrine
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Curved hemostat
- Iris scissors
- Ribbon gauze, plain or iodinated

- 2×2 gauze squares
- Adhesive tape
- Sterile saline
- Nylon sutures for skin closure, various sizes
- 3–0 Vicryl suture
- Needle driver

PATIENT PREPARATION

Explain and document the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Explain the postprocedure care. Obtain an informed consent for the procedure. Obtain an additional informed consent for the procedural sedation or nitrous oxide procedure if it applies. Wear a face mask, gown, and gloves for the entire procedure. The injection of local anesthetic solution can force abscess contents to shoot out. Incision of a tense abscess can also result in contamination of the Emergency Physician.

Antibiotic resistance is a growing concern. The incision and drainage of a simple and noncomplicated skin abscess does not require antibiotic therapy.^{7,8} The incision and drainage procedure, especially when forceful digital pressure is required, may release bacteria into the circulation. Consider the use of preprocedural intravenous antibiotics in patients suspected or known to be immunocompromised, with a history of prosthetic heart valve replacement, with a history of artificial joint replacement, or with signs of systemic toxicity.

Clean any dirt and debris from the skin overlying the abscess or cyst. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply drapes to delineate a procedural field and absorb any material or blood that escapes from the abscess cavity.

ANESTHESIA

Anesthesia is often difficult to obtain. Local anesthesia or specific nerve blocks should be considered the first choice. Direct infiltration of the skin and soft tissues in a fan-like pattern surrounding an abscess or “field block” provides sufficient anesthesia to tolerate the procedure (**Figure 136-3**).⁹ **Local anesthetics are weak acids,**

FIGURE 136-3. Field block anesthesia. **A.** Local anesthetic solution is infiltrated subcutaneously on all four sides of the infected sebaceous cyst. **B.** Local anesthetic solution is infiltrated deep to the infected sebaceous cyst in a fan-like pattern.

FIGURE 136-4. Subcutaneous infiltration of local anesthetic solution. The needle and syringe are held parallel to the skin. The needle is inserted into the subcutaneous tissue overlying the infected sebaceous cyst. Infiltrate the local anesthetic solution as the needle is withdrawn. The skin should blanch (shaded area) if injected properly. **A.** Superior view. **B.** Lateral view.

less effective in the acidic environment of an abscess, and should not be directly injected in the abscess cavity. The pain caused by injection of the local anesthetic solution is related to the rate that the anesthetic is injected and the force necessary to inject it. Inject the local anesthetic solution slowly through a small-bore needle (e.g., 25 to 30 gauge) as the needle is withdrawn through the dermis. The needle bore will create a passage through the subcutaneous tissue as it is inserted that enables the local anesthetic solution to be infiltrated slowly and with less discomfort.

Hold the syringe horizontally in reference to the skin surface. Inject 3 to 4 mL of local anesthetic solution intradermally over the dome of the abscess (**Figure 136-4**). The skin will blanch if the injection is given properly. The increased pressure within the cavity will cause more discomfort to the patient and may cause the solution to be forcefully expelled if there is an opening in the skin; therefore, some Emergency Physicians prefer to skip this step. Alternative anesthesia could be accomplished with regional or individual nerve blocks (Chapter 156) when the abscess is located in an anatomic area of innervation.

Systemic analgesia (i.e., procedural sedation, Chapter 159) is strongly recommended in the pediatric population and it may occasionally be required as well in adults when a field anesthesia has suboptimal results. In rare occasions, the procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.

TECHNIQUES

INCISION AND DRAINAGE

Several techniques have been described, such as the squeeze technique (i.e., cyst squeezed out through an elliptical or linear incision) and an oval incision at the top or around the punctum of the cyst to dissect it from the surrounding tissue to decrease scar tissue.^{10,11} A traditional technique is practical and effective when used in the Emergency Department.

Make a stab incision with a #11 scalpel blade in the skin overlying the area of fluctuance (**Figure 136-5A**). The incision should

FIGURE 136-5. Incision and drainage of an infected sebaceous cyst. **A.** A straight incision to drain the abscess. **B.** An elliptical incision to drain the abscess. **C.** The wound is irrigated with sterile saline. Pockets of purulent material are opened with the hemostat. **D.** The wound is packed open.

be parallel to any lines of tension to produce the least conspicuous scar, particularly in cosmetically important areas such as the face. Extend the incision the length of the fluctuant area with a #11 or #15 scalpel blade unless the abscess is in a cosmetically important area. A linear incision is adequate, although some advocate a cruciate incision. The cruciate incision results in greater scarring and is probably is not necessary. An elliptical incision can be performed in non-cosmetically important areas (**Figure 136-5B**). **The purpose of the elliptical incision is to remove a full-thickness wedge of tissue so that the wound will remain open. Limit the length of the incision on cosmetically important areas to 3 to 4 mm.** This is just large enough to drain the abscess.

Express the pus and the sebaceous material. It is too thick to drain spontaneously. It is important that loculations be lysed and the area be thoroughly drained to minimize recurrence. Insert a hemostat and spread the jaws within the cavity (**Figure 136-5C**). Useful technique employs gauze clamped in the jaws of a hemostat and swirled inside the abscess cavity to break adhesions and remove debris. Irrigate the cavity with normal saline solution (**Figure 136-5C**).

Loosely pack the wound cavity with ribbon gauze or gauze squares to prevent the skin edges from closing prematurely if a linear incision was made (**Figure 136-5D**). Cruciate and elliptical incisions do not require packing of the wound. Cover the wound with a bulky gauze dressing to soak up continued drainage.

INSERTION OF A de Pezzer CATHETER

A de Pezzer catheter is inserted by some to drain the infected sebaceous cyst.¹² Prepare the skin, incise the cavity with a stab incision, and insert a hemostat to break up the loculations and/or remove the capsule. Insert the de Pezzer catheter into the cavity. Use a size 10 to 16 French de Pezzer catheter depending on the size of the cavity. The de Pezzer catheter keeps the wound open while it heals without the use of packing. Place a safety pin or umbilical clamp on the catheter to prevent it from falling into the cavity. Trim the catheter just past the safety pin or umbilical clamp. Apply a dressing over the wound.

INCISION AND DRAINAGE WITH PRIMARY CYST REMOVAL

The entire sebaceous cyst, including the capsule, can be removed at the time of the incision and drainage with a simplified technique (Figure 136-2).¹³ Make an incision in the skin overlying the center of the sebaceous cyst. Extend the incision to be slightly longer than the diameter of the sebaceous cyst. **Do not cut into the dermis or subcutaneous tissues.** Sharply dissect the sebaceous cyst free of the surrounding subcutaneous tissues with an iris scissors. The delineation between the thin, shiny, white capsule and the surrounding tissues is very obvious. **Do not puncture the capsule of the sebaceous cyst.** Doing so and spilling some of the contents sets up a nidus for subsequent infection or reformation of the sebaceous cyst. Start at both ends of the incision and free the cyst circumferentially. Free the sides of the cyst from the surrounding adipose tissue. Gently grasp the top of the cyst with forceps or a hemostat. Elevate the cyst. Dissect the inferior border of the cyst free until it can be removed. Irrigate the wound with at least 200 mL of normal saline solution. Allow the cavity to heal by granulation. Alternatively, close the pocket with loosely applied 3–0 Vicryl deep sutures and approximate the skin edges with nylon sutures.

The cyst capsule can often rupture when attempting to remove it intact. If this occurs, express the contents as if incising and draining an abscess. Gently flush the cyst cavity with normal saline. Grasp the shiny, cut edges of the capsule with a hemostat. Gently elevate the cyst capsule edges and dissect the complete cyst capsule free from the surrounding adipose tissue. Irrigate the wound with at least 200 mL of normal saline solution. Allow the cavity to heal by granulation. Alternatively, close the pocket loosely with 3–0 Vicryl deep sutures and approximate the skin edges with nylon sutures.

Submit the complete cyst and capsule or the ruptured capsule for pathologic diagnosis in a sterile container. Several pathologic conditions can mimic a sebaceous cyst. This includes adenomas, adenocarcinomas, dermoids in children, and melanomas. Preauricular tender masses can be parotid gland tumors.

According to one study, this technique results in fewer days to heal, less pain for the patient, and less scarring than with incision and drainage alone.¹³ However, this was not a blinded study and no other studies could be found to verify the results. The researchers noted that primary resection (average of 50 minutes) takes longer than simple incision and drainage (average of 10 minutes). This may limit its use in the Emergency Department.

AFTERCARE

Antibiotics are generally unnecessary to treat a simple abscess unless there is cellulitis of the skin surrounding the wound.⁶ No data could be found regarding patients with an abscess who are diabetic, have cardiac valve disease, who have hardware in their body, or who are immunocompromised. These patients are at risk for infectious complications. It is advised to cover these patients with antibiotics. There are no data on the optimal duration of antibiotic treatment. The conventional 7 to 10 day course of antibiotic coverage is probably adequate.

Bacteriology of cutaneous abscesses remote from the rectum usually shows aerobic skin flora, with *Staphylococcus* and *Streptococcus* being the most common etiologies.⁸ Antibiotics recommended are a first-generation cephalosporin, a penicillinase-resistant penicillin, or a newer fluoroquinolone. Prescribe clindamycin, doxycycline, or trimethoprim-sulfamethoxazole if methicillin-resistant *Staphylococcus aureus* is suspected as the etiology.¹⁴

Instruct the patient to change the gauze dressing as often as necessary to keep the outside of the dressing dry. Patients should have scheduled follow-up in 48 hours for a wound check and removal of the packing. The packing should be removed in 24 hours if the

wound is on the face. Reinsert the packing upon follow-up if the skin closes on its own. Incisions that remain open or that have an elliptical or cruciate incision do not require packing. Advise the patient to change the packing every 24 to 48 hours depending on the amount of drainage. Decrease the amount of packing each time to allow the wound to heal from the base outward. The patient should thoroughly wash the wound with soap and water in the shower each time the packing is removed. It is helpful to let the stream of shower water run inside the wound to aid in wound irrigation. Discontinue the packing once the wound is well granulated and there is no concern that the skin edges will adhere to each other. The patient must continue to clean the wound thoroughly every day until it is fully healed.

Healing may take 1 to several weeks depending on the size of the abscess cavity, the patient's age, and any comorbidities. Instruct the patient to return to the Emergency Department immediately if they develop a fever, increased pain, or worsening redness of the skin surrounding the abscess. Pain relief can be provided with nonsteroidal anti-inflammatory drugs. Narcotic analgesics may occasionally be required in the first 24 hours after the procedure.

Inform the patient that incision and drainage in the acute care setting is not definitive treatment and that the condition is likely to recur unless the cyst is removed. Refer the patient to a physician who can provide wound care as well as remove the cyst capsule.

COMPLICATIONS

Sebaceous cyst infections may spread if the wound is inadequately drained. Attention must be paid to underlying anatomic structures (e.g., branches of cranial nerve VII) when draining facial abscesses to avoid complications caused by inadvertently incising these structures. Incomplete removal of the cyst wall or spillage of the cyst contents sets up a nidus for future infection and/or recurrence of the sebaceous cyst. A linear incision or too small of an incision can result in premature skin closure, incomplete healing of the cavity, and recurrence. Too large of an incision can result in delayed healing and significant scarring. Postprocedural bleeding is rare.

SUMMARY

Infected sebaceous cysts are commonly seen in the Emergency Department. They are thought to be due to blockage of the ducts of sebaceous glands that subsequently become infected and form an abscess. Most cutaneous abscesses can be drained in the Emergency Department. Consult a Surgeon for patients with large abscesses who require drainage in the Operating Room. Patients with signs of fever or toxicity should be admitted for parenteral antibiotics, incision and drainage, and observation. Refer patients to a physician who can provide wound care as well as definitive excision of the sebaceous cyst.

Hemorrhage Control

Christopher Freeman and Ariana Wilkinson

INTRODUCTION

Control of external hemorrhage from an injury is a priority of basic first aid. It begins with first responders before arrival at the hospital and continues with Physicians in the resuscitation suite (**Figure 137-1**). Bleeding from extremity wounds is common. Most bleeding is a minor inconvenience for the busy Emergency Physician in the crowded Emergency Department, prolonging wound closure and complicating wound healing. Major exsanguinating hemorrhage can be life-threatening. Hemorrhage from extremity injuries was a leading cause of death in the Vietnam War and Operation Desert Storm.^{1,2} Hemorrhage remained the leading cause of death in Operation Iraqi Freedom and Operation Enduring Freedom, with torso hemorrhage leading the deaths.³ **Methods for rapid and effective control of bleeding are essential in managing traumatic injuries and optimizing wound management.**

ANATOMY AND PATHOPHYSIOLOGY

Hemostasis is the first biological response to injury.⁴⁻⁶ Hemostatic platelet plugs form at the ends of transected vessels within seconds of traumatic disruption of the skin. Fibrin fibers gather about the platelet plug within minutes. This fibrin mesh becomes part of an early matrix that initiates wound healing.⁴

Hemostasis is the priority in wound management for the Emergency Physician caring for traumatic wounds.⁷ Control of bleeding is necessary to establish hemodynamic stability and prevent further blood loss (Figure 137-1). Hemostasis is the first step in preparing for wound closure. Inadequate hemostasis with hematoma formation impairs wound healing, increases the risk of wound infection, leads to tissue ischemia, and results in hypertrophic scars.^{8,9} Large hematomas may cause delayed wound dehiscence.

Bleeding from wounds may be superficial or deep. Superficial wounds (e.g., abrasions, avulsions, or simple lacerations) involve damage to the epidermis, dermis, and subcutaneous tissue. Bleeding from most superficial wounds is predominantly from capillaries, small veins, or arterioles. Wounds deep to the fascia involve larger vessels and are typical of deep punctures, gunshot wounds, major crush injuries, and stab wounds. The approach to the bleeding wound will depend upon the nature of bleeding (e.g., large vessel versus small, discrete source versus diffuse), the site of injury, and its association with other major organ injury (**Figure 137-2**).

FIGURE 137-1. A traumatic amputation with a SWAT-T Tourniquet. (Courtesy of TEMS Solutions LLC, Abingdon, VA.)

INDICATIONS

The immediate control of excessive bleeding is always a priority during the first contact with the patient. **All bleeding must be controlled (Figure 137-2).** Exsanguinating hemorrhage must be immediately controlled. All other bleeding can wait until the ABCs (airway, breathing, and circulation) and life-threatening conditions are addressed. The timing and selection of specific measures to isolate and treat the bleeding source will depend upon the management priorities for each patient. A simple compressive dressing or tourniquet may be used as a first-line measure to control bleeding in the multiple trauma patient. Definitive measures may be taken early to identify and treat isolated specific injuries.

CONTRAINDICATIONS

There are no absolute contraindications to any technique of bleeding control.⁷ Choose the technique best suited to the individual situation. **An impressive wound should not distract or divert attention away from other injuries that may be less dramatic but more immediately life-threatening. Use the simplest and most effective techniques to control hemorrhage when faced with multiple injuries.**

EQUIPMENT

■ PRESSURE CONTROL

- Blood pressure cuff
- Sterile 4×4 gauze pads
- Elastic bandage
- Tourniquet, limb and junctional

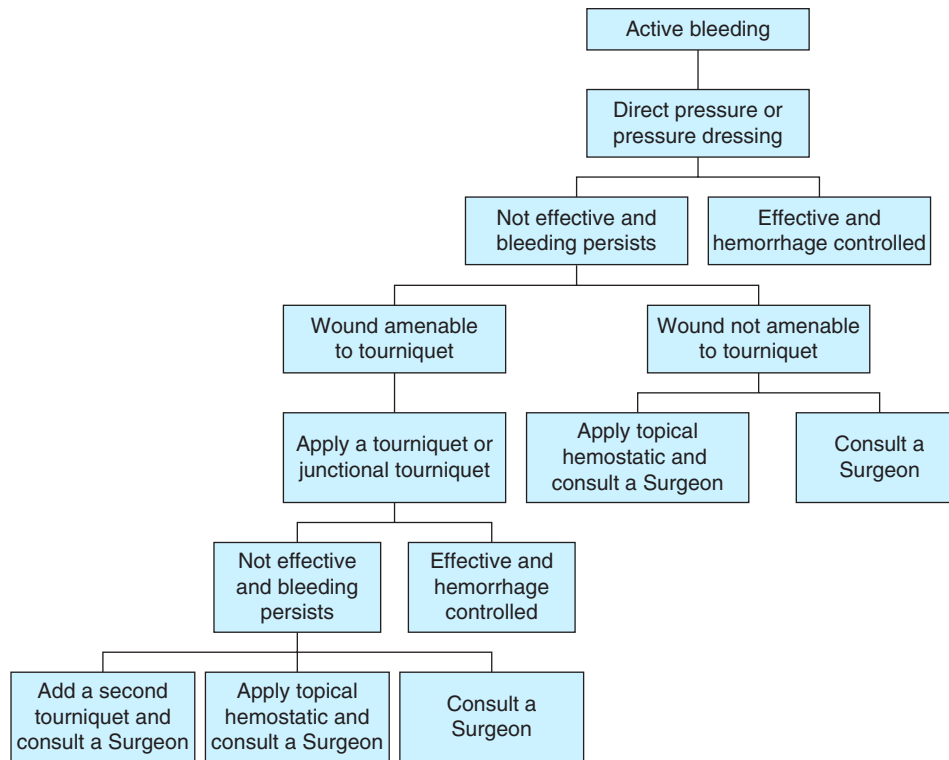

FIGURE 137-2. An algorithm for hemorrhage control.

■ WOUND MANIPULATION

- Hemostats
- Needle driver
- Assorted suture
- Scissors
- Sterile saline
- 20 mL syringes
- 10 mL syringes
- 18 gauge needles
- 27 gauge needles

■ ANESTHETICS

- Lidocaine, with and without epinephrine
- Bupivacaine, with and without epinephrine
- 18 gauge needles
- 27 gauge needles
- 10 mL syringes

■ WOUND CAUTERY

- Silver nitrate (AgNO_3)
- Electrocautery unit
- Monsel's solution (i.e., 20% ferric subsulfate solution)
- Drysol (i.e., 30% aluminum chloride solution)

■ VASOCONSTRICTORS

- 1:1000 epinephrine
- 1% to 4% cocaine
- Tetracaine, epinephrine, and cocaine (i.e., TEC or TAC) solution

■ TOPICAL HEMOSTATIC AGENTS

- Gelfoam
- Surgicel
- Cellulose
- Dry gelatin
- Thrombin
- Microfibrillar collagen
- Cyanoacrylate
- Various agents as listed in the techniques section

■ MISCELLANEOUS SUPPLIES

- Povidone iodine or chlorhexidine solution
- Penrose drain
- Finger tourniquet
- Hemoclips
- Hemoclip applicator
- Bone wax
- Raney scalp clips and applier
- Resuscitative endovascular balloon occlusion of the aorta supplies (Chapter 74)
- Tranexamic acid

PATIENT PREPARATION

Control of hemorrhage is the priority. Attention to wound preparation should not delay definitive action to control heavy bleeding. Obtain intravenous access and a type and crossmatch for blood products in any patient with active bleeding and hemodynamic compromise while applying direct pressure to the bleeding site. Explain the procedures to the heavily bleeding patient while

preparing for and performing the procedures. There is no need to obtain an informed consent for the procedure if the bleeding is heavy. Document this in the medical record. Explain the risks, benefits, and alternative procedures to the patient and/or their representative if the bleeding is minimal. Obtain an informed consent for the procedure and place this in the medical record.

Administer a local anesthetic prior to significant wound manipulation if the injury is minor and the patient is stable. Irrigate contaminated wounds free of foreign bodies and debris. Clean the surrounding area with an antiseptic solution (e.g., povidone iodine or chlorhexidine). Refer to Chapter 114 for the complete details of wound cleansing and preparation.

TECHNIQUES

DIRECT PRESSURE

The quickest and easiest method to stop bleeding is the application of direct pressure to the bleeding site.¹⁰⁻¹² Poor lighting may prevent exposure and visualization necessary to identify discrete bleeding sites before hospital arrival. A compressive dressing may be the best option to initially control bleeding. **Many compressive bandages apply too little pressure over too wide an area and act more like a sponge than a pressure dressing. Significant blood loss can be hidden within a bulky pressure dressing.**

Explore a bleeding wound as soon as lighting is sufficient and circumstances allow. **Brisk bleeding frequently has a few discrete sources that can be easily managed once identified.** Direct pressure over bleeding vessels allows time for a platelet plug to form and gives a chance for the body's natural mechanisms of hemostasis. Apply pressure over arterial wounds for 10 to 15 minutes to control most bleeding. Apply pressure to a proximal artery to impede arterial inflow and control, or slow, the bleeding when wound exploration is not practical.^{13,14}

TOURNIQUETS

The use of tourniquets for extremity hemorrhage has received a great deal of attention throughout history. **Tourniquets are seldom necessary to control hemorrhage.¹⁵ Direct pressure is more effective and causes less tissue ischemia.** Tourniquets may be required to control bleeding and free personnel to attend to other concerns if there is significant bleeding. Use tourniquets as a last resort when other methods fail and the patient's life is in jeopardy.^{13,15} The correct application of a tourniquet causes the patient pain. **Do not remove the tourniquet.** It is placed to prevent exsanguination. Some of the currently available tourniquets include the Combat Application Tourniquet (Composite Resources, Rock Hill, SC), the Special Operations Forces Tactical Tourniquet (Tactical Medical Solutions, Anderson, SC), and the Emergency and Military Tourniquet (Delfi Medical, Vancouver, Canada).

Many mistakes are made with tourniquets (Table 137-1). This includes not taking off the tourniquet within 2 hours, not tightening the tourniquet enough, taking the tourniquet off too soon, and restoring blood flow to the limb before tourniquet damage. The complications associated with a tourniquet are listed in Table 137-2.

There is no definitive time to safely apply a tourniquet. There is a risk of limb ischemia and eventual limb loss any time a tourniquet is used.⁷ It is generally accepted that 2 hours is a safe time.¹⁶⁻¹⁸ It is believed that beyond this time permanent muscular or neurologic injury may occur. A tourniquet has been safely applied for up to 6 hours without permanent complications in some cases.¹⁸⁻²⁰ **Use the minimal tourniquet pressure necessary to maintain hemostasis. Release the tourniquet periodically and reassess the extremity.**

TABLE 137-1 Common Errors of Using a Tourniquet

Not making the tourniquet tight enough
Not taking the tourniquet off when not needed
Not using a second tourniquet if needed
Not using a tourniquet when indicated
Periodically loosening the tourniquet
Placing a tourniquet too proximally with distal bleeds
Removal of the tourniquet by emergency medical services
Removing the tourniquet if the patient complains of pain
Removal of the tourniquet if the extremity is amputated
Removing the tourniquet if other hemorrhage control methods are contraindicated
Removing the tourniquet within 2 hours if bleeding is not controlled
Removing the tourniquet if the wound cannot be reexamined
Removing the tourniquet when the patient is in shock
Using a tourniquet for minimal bleeding
Waiting too long to place the tourniquet

It is best to limit the use of a tourniquet for the minimum time required to temporarily be lifesaving and until definitive care can be received.

JUNCTIONAL TOURNIQUETS

Junction hemorrhage or proximal extremity hemorrhage is the most common cause of death from compressible hemorrhage. **Junctional hemorrhage is defined as hemorrhage from the junction of the torso and extremity or proximal extremity where a traditional tourniquet is unable to be applied.²¹** Topical hemostatic agents, direct pressure, or a combination were used for junctional hemorrhage without much success.

There are now four devices that have been approved by the Food and Drug Administration (FDA) for junctional hemorrhage control in the military and prehospital setting.²²⁻²⁴ These devices are easy and safe to use, effective, low in cost, lightweight, quickly applied, and small. **These devices, like extremity tourniquets, are not meant as an alternative to surgical intervention but are a bridge to definitive treatment.**

The Abdominal Aortic and Junctional Tourniquet (AAJT) is a pneumatic belt that allows for prolonged delivery of pressure on

TABLE 137-2 Complications of Using a Tourniquet

Local
Bone injury
Compartment syndrome
Delayed recovery
Neurapraxia from compression

one area (Compression Works LLC, Birmingham, AL).^{25,26} The circumferential device uses a belt, windlass, and pneumatic pressure to compress the aorta (**Figure 137-3**). It can be used up to 4 hours. The wedge-shaped bladder provides pressure over a large surface area and allows a lower overall tissue pressure than other junctional tourniquets. A case report from Afghanistan showed safe and effective cessation of severe internal bleeding from an unknown battlefield injury after the patient became bradycardic with impending cardiac arrest.²⁴ The AAJT effectively tamponades the abdominal aorta. This device may show some utility in the management of severe pelvic bleeding as the internal iliac artery branches off the aorta distal to the area of occlusion and can stabilize the pelvis.

The AAJT is simple to apply. Place the belt of the of the AAJT around the abdomen with the inflatable cuff overlying the umbilicus. Manually tighten the buckle of the belt. Further tighten it with a windlass device located on the front of the belt. Inflate the cuff. The AAJT can be used for upper extremity junctional hemorrhage by placing it in the axilla.

The Combat Ready Clamp (CroC) is designed for control of junctional hemorrhage in the inguinal and axillary area (Combat Medical Systems, Harrisburg, NC).²⁶⁻³⁰ This device was created to exert mechanical pressure with plastic circular discs directly over a junctional wound or indirectly over proximal vessels to occlude blood flow to the wound (**Figure 137-4**). The disc is tightened down onto the desired area by turning a handle attached to a metal vertical rod. There is currently limited evidence on its use. A study

FIGURE 137-4. The Combat Ready Clamp (CroC). (Courtesy of Combat Medical Systems, Harrisburg, NC.)

FIGURE 137-5. The Junctional Emergency Treatment Tool (JETT). (Courtesy of North American Rescue LLC, Greer, SC.)

showed the CroC had 100% efficacy for stopping axillary junctional hemorrhage.³¹

The Junctional Emergency Treatment Tool (JETT) was developed by the University of Texas Health Science Center for Translational Injury Research and North American Rescue Products LLC (Greer, SC). The JETT is for use only with inguinal junctional hemorrhage.²⁶ It is unique in that it has a pelvic binder component and has the capability to compress one or both femoral arteries (**Figure 137-5**). The JETT uses a windlass mechanism to cinch down the device and mechanically provide direct pressure.

The SAM Junctional Tourniquet was approved by the FDA for axillary hemorrhage, lower extremity junctional hemorrhage, and unstable pelvic fractures (SAM Medical Products, Wilsonville, OR).^{26,28,32} It is effective at controlling bleeding in proximal limbs or other high-level amputations.²⁷ It contains a belt that is fastened around the abdomen or pelvis and two inflatable cuffs known as Target Compression Devices (TCDs) (**Figure 137-6**). The TCDs are placed proximal to the injury and inflated to effectively occlude blood flow. A case report showed the efficacy of the SAM Junctional Tourniquet in the battlefield for severe inguinal hemorrhage.³³

Junctional tourniquets have advantages and disadvantages. Additional benefits of junctional tourniquets are that they can be used as pelvic binders and may aid in tamponade of severe pelvic bleeding from pelvic fractures. Complications of junctional

FIGURE 137-6. SAM Junctional Tourniquet. (Courtesy of SAM Medical, Wilsonville, OR.)

tourniquets include ischemic injury if left on too long and continued hemorrhage if applied incorrectly. There are otherwise very few risks to applying these devices. Junctional tourniquets have safe application times between 1 and 4 hours and are used only as a temporizing measure to get patients definitive care in the Operating Room.³⁴ None of these devices have been studied in prospective or randomized controlled trials. The only studies available are animal studies, manikin bleeding models, or case reports. The implementation by trained professionals in the correct setting could be lifesaving.³⁵

EXTREMITY TOURNIQUETS

The use of extremity tourniquets is not new. Much of the literature supporting the use of extremity tourniquets has been produced by the military.³⁶⁻³⁸ Civilians have close access to prehospital providers who can focus on hemorrhage control. Civilian extremity injuries are often less severe than those seen in war. Despite this, the application of an extremity tourniquet can be lifesaving for civilians. Below is a representative sample of extremity tourniquets.

The Basic Windlass Tourniquet (TBWT) is a reusable tourniquet (rthInnovations LLC, Gloucester, VA). It is made of a heavy-duty polypropylene weave with a breaking strength of 1200 pounds (**Figure 137-7**). The TBWT does not require clips, knots, pins, or ties to secure the device.

The SWAT-T tourniquet is a single-use device (TEMS Solutions, Abingdon, VA). It is composed of elastic that wraps around an extremity (**Figure 137-8**). The SWAT-T is easy to apply in seconds with little prior training. It is effective in wet conditions. Application requires two hands.

The Combat Application Tourniquet (C-A-T) was designed for one-handed use (North American Rescue LLC, Greer, SC). It has been used by the United States Army in the field. It applies quickly with minimal prior training. It has a Velcro retention strap and windlass mechanism that locks in place (**Figure 137-9**).

The SAM XT is a single-use tourniquet (SAM Medical, Wilsonville, OR). It uses a buckle to clamp on the extremity and a windlass mechanism to tighten (**Figure 137-10**). The device requires simple training and is easy and quick to apply. It is made of nylon and auto-locks upon tightening to eliminate slack.

BANDAGES

These devices include the Emergency Bandage (PerSys Medical Co., Houston, TX), H-Bandage (H and H Medical Corp., Williamsburg, VA), and the WoundStop (PerSys Medical Co., Houston, TX) (**Figure 137-11**). These consist of an elastic-containing compression bandage, similar to an Ace wrap, and a nonadherent pad. The single-use bandages are quick and easy to apply with two hands. The bandages are sterile and single-use. Place the pad over the bleeding site and tightly wrap the bandage around the extremity. Secure the end of the bandage.

BALLOON CATHETERS

Physicians have been using balloon catheters to tamponade exsanguinating bleeding from deep wounds or wound tracks.^{39,40} Devices used include Fogarty catheters, Foley catheters, and Sengstaken-Blakemore tubes. Balloon catheters are blindly placed in the wound and inflated to tamponade bleeding. These devices are not specifically designed for this purpose. **They are used as an improvised technique to temporarily tamponade the hemorrhage.** Reviews have shown that balloon tamponade was useful in the initial control of bleeding from limbs and intraabdominal sources.⁴¹

Tourniquets specific for deep wound hemorrhage are being developed. These devices may be used when conventional external methods (e.g., clotting agents, direct pressure, and tourniquets) do not control the hemorrhage. This group of devices are inserted into the wound or wound track and inflated to tamponade the bleeding. One of these devices is the TourniCath (CardioCommand Inc., Tampa, FL). It uses a double-walled cylindrical balloon to cause wound track compression

(**Figure 137-12**). It was designed to insert easily into the wound tract and is inflated up to 400 mL. The device measures 8×2 inches when inflated. These devices have not yet been fully evaluated for use in the prehospital setting or the Emergency Department.

SUTURE LIGATION

Thoroughly inspect briskly bleeding wounds. Place a blood pressure cuff proximally and inflate it until a dry bloodless field is obtained. Large-vessel bleeding will first become apparent as the cuff pressure is slowly dropped. **Large and intermediate-sized vessels will need to be ligated or oversewn for effective control.** Familiarity with the vascular supply to the extremities will help the Emergency Physician anticipate major arterial injuries and look for likely bleeding sources. **Search for the ends of a blood vessel whenever a transected vessel is seen.** A retracted artery in spasm will likely bleed later. Actively search for blood vessel ends and ligate them.

Ligate bleeding vessels that can be visualized (**Figure 137-13**). Grasp the cut end of the bleeding vessel with a hemostat (**Figure 137-13A**). Pass an appropriate-sized suture around the vessel (**Figure 137-13B**). Use absorbable sutures that do not lose their tensile strength too soon (e.g., Vicryl, Monocryl, and PDS). Tie and secure the suture around the base of the bleeding vessel (**Figure 137-13C**). Gently release the hemostat from the blood vessel.

Cut blood vessels, especially arteries and arterioles, often retract into the tissue and are difficult to visualize. A suture can be used to control the bleeding (**Figure 137-14**). Place a figure-of-eight stitch (**Figure 137-14A**) or a purse-string stitch (**Figure 137-14B**) to

FIGURE 137-14. Control of a bleeding vessel deep or embedded in tissue. **A.** The figure-of-eight stitch. **B.** The purse-string stitch. Note that both of these stitches are not tied tightly for the sake of clarity. In real use, both of these stitches will be tied tightly to seal the bleeding vessel.

encompass the blood vessel. These sutures are easy to place, quick, and simple.

CAUTERY

Place a blood pressure cuff proximally and inflate it until a dry bloodless field is obtained. Slowly deflate the blood pressure cuff. Identify small bleeding vessels as the pressure is gradually reduced. **The most likely source of significant bleeding is from dermal arterioles and veins.** Venous bleeding usually stops with direct pressure. Dermal arterioles tend to resist direct pressure and cause persistent oozing from the wound edges. Blood vessels are best identified by picking up the wound edge and inspecting the dermis. Bleeding vessels can be effectively treated with electrocautery or chemical cauterization.

Electrocautery is surprisingly easy and effective against aggressive bleeding from small vessels less than 2 mm in diameter.¹⁰ Handheld battery-driven electrocautery units use a heated electrode to deliver a thermal burn to the tissue and char the ends of vessels (**Figure 137-15**). They are simple to use, inexpensive, and stocked in most Emergency Departments. More versatile electro-surgical units (e.g., the Bovie and Hyfrecator) are extremely effective coagulators.⁴² These devices are in the Operating Rooms but are not routinely available in most Emergency Departments.

FIGURE 137-13. Control of the bleeding vessel that is visualized. **A.** Clamp the cut end of the vessel with a hemostat. **B.** Wrap a suture ligature about the base of the vessel. **C.** Tie and secure the suture around the base of the bleeding vessel.

FIGURE 137-15. The battery-powered electrocautery device.

Chemical cauterization with silver nitrate (AgNO_3) is an effective alternative. The silver nitrate is a dark material that is provided on the end of a wooden applicator stick and resembles a large matchstick (**Figure 137-16**). Rub the silver nitrate over the cut end of the vessel. It forms an insoluble precipitate with tissue protein to form an artificial clot or an eschar that occludes the vessel lumen. **Silver nitrate cannot be used on briskly bleeding vessels as it will coagulate the blood and not the vessel.** The cut vessel must not be bleeding or be just oozing for silver nitrate to coagulate the tissue.

The reduced silver nitrate salts stain the tissue they contact black. Most of the black silver salts are resorbed by the body over several weeks. There is the possibility of permanent staining or tattooing of the skin. **Do not use silver nitrate on light-skinned individuals or close to the skin surface in cosmetically sensitive areas.** Minimize tissue contact with silver nitrate to prevent damage to the underlying tissue.

Two topical solutions can be used for chemical cauterization. Monsel's solution is a 20% ferric subsulfate solution that is thick and dark brown to black in color. **It can permanently stain or tattoo the skin.** Drysol solution is a 30% aluminum chloride solution that is colorless. It will not stain or tattoo the skin. Drysol solution may not be as effective as Monsel's solution for cauterization. Both solutions are applied to a relatively dry or slightly moist area with a cotton-tipped applicator.

Briefly apply the electrocautery or chemical cautery directly to the bleeding source. Neither technique will work well unless the field is dry. This can be achieved with the use of suction, or the wound can be dabbed dry with gauze or cotton-tipped applicators or external pressure. More liberal use to the surrounding tissue will leave unnecessary damage and impair wound healing. Overzealous use of electrocautery and chemical cautery can cause unnecessary tissue necrosis and increase the risk of infection.

VASOCONSTRICTORS

Smaller bleeding vessels will usually constrict and eventually stop on their own once major vessels have been treated. The use of local vasoconstrictors and topical hemostatic agents is effective.⁴³

FIGURE 137-16. The silver nitrate (AgNO_3) applicator.

Epinephrine is a convenient and effective vasoconstrictor.⁴⁴ It can be injected into the wound edges with a local anesthetic or placed directly into the wound. Do not use epinephrine and other vasoconstrictors in a finger, toe, ear, nose, or penis where ischemia may cause tissue loss. **Use topical vasoconstrictors with diligent attention to the total dose administered to avoid systemic side effects (e.g., hypertension, tachycardia, and seizures).**

Commonly available local anesthetic solutions containing epinephrine that are available in the Emergency Department include lidocaine and bupivacaine. Inject 1 to 2 mL of local anesthetic solution containing epinephrine into the tissue surrounding the bleeding vessel, cover the wound with saline-moistened gauze, and apply external pressure for 2 to 4 minutes. **Use caution and aspirate prior to the injection to ensure that the solution is not being injected intravascularly.** Alternatively, spray 1 to 2 mL of 1:1000 epinephrine or an epinephrine-containing local anesthetic solution over the wound surface with a 25 gauge needle, cover the wound with a sterile saline-moistened gauze, and apply external pressure for 2 to 4 minutes.⁴⁵

A more dilute epinephrine solution can be used in larger wounds to minimize potential side effects. Solutions as dilute as 1:100,000 to 1:1,000,000 are used to control brisk bleeding that accompanies tangential burn wound excision and graft donor sites.⁴⁶ Topical cocaine (1% to 4%) is a potent vasoconstrictor commonly used on mucous membranes. Combinations of 0.5% tetracaine, 1:2000 epinephrine (adrenalin), and 11.8% cocaine (TEC or TAC) are used for topical anesthesia and hemostasis in pediatric wounds.⁴⁷ Apply 1 to 2 mL of these solutions directly into the wound followed by an occlusive dressing.

TOPICAL HEMOSTATIC AGENTS

This group of agents has seen most of the recent innovation in hemorrhage control (**Table 137-3**). Most of these agents were originally developed for operative hemostasis. Their use has expanded into the Emergency Department. More and more hemostatic agents are being developed for hemorrhage control outside the Operating Room or for life-threatening hemorrhage when standard agents have failed. Topical hemostatic agents used in the Emergency Department include cellulose, cyanoacrylate tissue adhesive, dry gelatin, inorganic agents, microfibrillar collagen, polysaccharide-based agents, and thrombin. **Use of hemostatic agents does not replace a methodical approach to wound care and a meticulous search for bleeding vessels.**

Oxidized cellulose (i.e., Surgicel) or dry gelatin (e.g., Gelfoam or Surgifoam) based agents can be used to provide hemostasis when there is diffuse oozing, especially where a small amount of blood impedes wound closure and jeopardizes cosmetic outcome. These agents provide a matrix for platelet deposition and aid hemostasis.^{8,43} Troublesome wounds can be treated with these agents and covered with a pressure dressing. The dry field can be approximated with sutures after a few minutes. Another option is to leave the hemostatic agent in the wound, close the wound, and apply a pressure dressing. These techniques will be effective for many wounds. These agents are not free of complications. Absorbable gelatin in a wound can produce excessive granulation tissue and fibrosis. Cellulose can cause a foreign body reaction.

Topical thrombin and microfibrillar collagen (e.g., Avitene, Instat, and Helistat) may be useful hemostatic agents in problematic cases with persistent bleeding.^{43,48} Apply topical thrombin in powder form or spray diluted thrombin on the wound. Concentrations of 100 units/mL of thrombin are usually effective. Concentrations of 1000 to 2000 units/mL can be used if the bleeding is severe. Microfibrillar collagen can be used to encourage platelet aggregation. Thrombin and microfibrillar collagen are expensive and are not

TABLE 137-3 Characteristics of Topical Hemostatic Agents

Agent	Active ingredient	How supplied	Advantages	Disadvantages
Celox	Chitosan derivative	Granular powder	Antimicrobial Inexpensive	Difficult application
Combat Gauze	Kaolin	Impregnated gauze	No exothermic production	Gauze roll
Dry Fibrin Sealant Dressing (DFSD)	Calcium chloride Human fibrinogen Human thrombin Vicryl mesh	Block on a compression bandage	Self-polymerizes	Costly Dry field works best Requires careful handling
Hemcon	Chitosan	Pads	Antibacterial Antifungal Well-tested	Can stick to gloves Must apply quickly
Quikclot	Zeolite	Gauze impregnated Powder	Gauze easy to handle	Messy powder form Produces heat
SuperQR	Potassium iron oxyacid salt Hydrophilic polymers	Powder	Effective for bleeding	Difficult application Produces heat
Trauma Stat	Chitosan derivative Polyethylene fibers Silica	Gauze	Can be packed into wounds	Gauze roll
Woundstat	Absorbent polymer Smectite	Granules	Effective for bleeding	Difficult application Small wounds

usually supplied outside the Operating Room. Limit their use to the patient with a coagulopathy or severe bleeding unresponsive to other measures.

Cyanoacrylate tissue adhesive (e.g., Dermabond and Orobond) is commonly used in the Emergency Department for wound closure. It is a helpful adjuvant for hemostasis. It forms an occlusive dressing that provides hemostasis. There are few human data demonstrating the hemostatic activity of cyanoacrylate. It has been shown to promote clot formation, decrease bleeding time, and decrease rebleeding in porcine models for epistaxis and femoral arterial injury.^{49,50} Cyanoacrylate works best in a dry, bloodless field that can be obtained by a combination of direct pressure, irrigation, and temporary tourniquet use. Hemostasis was achieved in a porcine arterial hemorrhage model in 90% of the animals after temporary tourniquet placement, irrigation, and cyanoacrylate application via spray.⁵⁰ The wound can remain uncovered after cyanoacrylate application, allowing for easier recognition of rebleeding.

A relatively new area in topical hemostasis is the management of life-threatening bleeding outside of the Operating Room. This has focused on hemostatic dressings and agents leading to rapid hemorrhage control after application. These products are placed in the wound, covered with gauze, and pressure is applied. More definitive management can be planned after hemostasis is achieved. These agents fit into the broad categories of inorganic and polysaccharide-based hemostatic agents.

The inorganic hemostatic agents include Quikclot Combat Gauze (Z-Medica, Wallingford, CT). The original Quikclot is a zeolite powder that adsorbs water and produces an exothermic reaction.⁵¹ The newer Quikclot products are kaolin based. Kaolin is an inorganic compound that activates the intrinsic clotting cascade and promotes clot formation. Quikclot Combat Gauze is a gauze roll impregnated with kaolin nanoparticulate minerals. The gauze is packed into the wound and pressure is applied until hemostasis is achieved. Human studies are limited. There are case series showing high rates of hemorrhage control in junctional and nonjunctional extremity applications.⁵²

Self-expanding hemostatic polymer is a compound that contains a highly absorbent polymer capable of absorbing 30 gm of water for each gram of polymer and a wicking binder. This is contained within a 4 inch microporous nylon bag. It swells rapidly when exposed to liquids and produces a tamponading effect in the wound bed.

The polysaccharide-based agents are classified as *N*-acetylglucosamines containing glycosaminoglycans and microporous polysaccharide hemispheres. The data supporting the use of these agents are limited and mostly derived from animal studies with multiple differing models, making direct comparison between the products difficult. *N*-acetylglucosamine glycosaminoglycans are complex polysaccharides derived from marine microalgae or crustacean shells in the form of chitin or chitosan.⁵³ These agents are thought to provide hemostasis through multiple mechanisms including attraction of circulating red blood cells, tissue adhesion, and vasospasm.⁵⁴ *N*-acetylglucosamine-based agents include Hemcon ChitoGauze (Tricol, Portland OR), Celox (SAM Medical Products, Portland OR), and Modified Rapid Deployment Hemostat (MRDH) (Marine Polymer Technologies, Danvers MA). Hemcon ChitoGauze is available as a coated bandage. Celox is available as granules, granules in a disposable bag, coated flexible gauze, and a plunger for deep application. MRDH is available as a coated gauze. Hemcon ChitoGauze, one of the best-studied agents, has demonstrated mixed results in animal studies but has favorable reports from its limited use in the United States military.⁵⁵ There have been prehospital studies of ChitoGauze showing effectiveness in anticoagulated patients with an 89% rate of cessation or slowing of bleeding.⁵⁶ A limited study of 10 trauma patients with intraabdominal injuries achieved hemostasis in 90% of the patients with MRDH.⁵⁷

The last type of hemostatic agent and dressings are the procoagulant supplements. They include Dry Fibrin Sealant Dressing (DFSD) and SeraSeal (Wortham Laboratories, Chattanooga, TN). DFSD is composed of clotting proteins purified from donated blood and plasma. The DFSD is a multilayered dressing composed of fibrin, calcium chloride, thrombin, and an absorbable mesh. The dressing combines with blood to become activated and adherent to the tissues. DFSDs require special handling and are very expensive, both of which will limit its use in the Emergency Department. SeraSeal is an FDA-approved clotting factor product derived from cows. This compound contains activated factors II, V, VIII, and XIII in an agar matrix. SeraSeal is applied as drops to the site of active bleeding and promotes the formation of a clot. The studies of effectiveness are scant and its role in the Emergency Department is limited.

The limited human evidence, case reports, and small animal studies make comparison of the various hemostatic agents difficult. The application of these agents is simple. Determining which of these

agents to use is difficult and is guided by local availability and by personal experience with these products. These agents are useful adjuncts in topical hemostasis in the early phase of trauma management in the Emergency Department.

TRANEXAMIC ACID

Tranexamic acid (TXA) is an antifibrinolytic agent that inhibits plasminogen activation. It stops the conversion of plasminogen to plasmin. The main indications for TXA are dental postextraction bleeding, epistaxis, and severe trauma with bleeding. TXA is contraindicated if the patient is allergic to it or has a thrombosis (e.g., arterial and venous). TXA can cause allergic reactions, thrombosis, and toxic epidermal necrolysis.^{58,59}

TXA can be used topically for the control of hemorrhage.⁵⁹ TXA is available in 100 mg/mL intravenous solution and 650 mg tablets. Soak gauze in liquid TXA, put the gauze in the wound, and cover the wound with a compression dressing. The tablets are much less expensive than the liquid. The tablets can be crushed and placed directly in the wound followed by application of a compression dressing. A paste can be made from the tablets. Crush three tablets of TXA. Add 0.5 mL aliquots of sterile water and mix well. Continue to add sterile water in aliquots up to 3 mL and mix after each water addition until a thick paste is formed. Apply the paste to the wound followed by a compression dressing. Allow the TXA 20 to 30 minutes to work and stop the bleeding. Remove the compression bandage and reevaluate the wound. Remove the TXA if the bleeding has stopped. The powder and paste may be difficult to remove.

ENDOVASCULAR DEVICES

Severe hemorrhage uncontrollable by traditional techniques of direct pressure, tourniquets, and hemostatic agents can be controlled with minimally invasive nonoperative hemostatic tools. Endovascular tools may be used to tamponade bleeding by intrinsically clamping the aorta. Similar tools were first used during resuscitation of ruptured abdominal aortic aneurysms. The resuscitative endovascular balloon occlusion of the aorta (REBOA) device has been successfully implemented in cases of severe life-threatening hemorrhage. This device can be used as an alternative to thoracotomy with aortic cross clamping by providing proximal aortic pressure. REBOA has less physiologic disturbance and higher success rates than aortic cross clamping.

The indication for placement of a REBOA catheter is life-threatening intraabdominal or pelvic hemorrhage where immediate operative control cannot be obtained. It is indicated for bleeding unable to be controlled by less invasive measures (e.g., direct pressure). This is a temporizing measure to stabilize a hemorrhaging patient while definitive methods of hemorrhage control are pursued. See Chapter 74 for the complete details of using REBOA. A brief description is included below.

REBOA can be introduced through the femoral artery using a Seldinger technique under ultrasound guidance. A guidewire is then placed, followed by a 12 French catheter and a 9 French balloon catheter. This procedure is commonly performed under fluoroscopic guidance. There are new kits available that do not require fluoroscopy and allow the operator to insert the device in one pass via an 8 French catheter in the femoral artery. Proper placement in the thoracic aorta was estimated by measuring the distance between the inguinal crease and the midsternum. A study showed a successful placement rate of 87.5% with the fluoroscopy-free technique.⁶⁰ Another study examined the use of ultrasound to determine the proper location of the contrast-filled balloon catheter.⁶¹ Ultrasound-guided placement is faster and safer than the traditional technique and has the distinct benefit of not requiring fluoroscopy to determine placement.⁶¹

There are three different zones of the aorta for the balloon. Zone 1 is the area distal to the left subclavian artery and proximal to the celiac trunk. Zone 2 represents a 3 cm area of the aorta distal to the celiac trunk and proximal to the last renal artery. Zone 3 represents the aorta distal to the renal arteries and extends to the bifurcation into the common iliac arteries. Any of these three zones can be targeted with this technique, but zones 1 and 3 are the most commonly targeted.⁶²

There is no definitive time to safely apply REBOA. **There is a risk of ischemia and aortic injury any time REBOA is used.** The least amount of time used the better. Times of 60 minutes or less are thought to be safe.⁶³ The rates of organ dysfunction and failure, especially kidney failure, increased significantly with times of greater than 90 minutes.

The REBOA device may be used as a bridge to surgery or to interventional vascular procedures for embolization of severe pelvic or splenic bleeding. REBOA may be implemented in the prehospital setting.⁶⁴ These devices are primarily used in trauma care. REBOA can be used in nontraumatic cases (e.g., pelvic hemorrhage). Pelvic hemorrhage is hard to access surgically and is generally managed endovascularly. REBOA would likely be the best temporizing measure for hemorrhage.⁶⁵

The main risks are the same with any procedure where a vessel is accessed. They include bleeding, damage to surrounding structures, and infection. One complication unique to the REBOA is rupture of the aorta due to overinflation of the balloon.

REBOA is a newer technique for hard-to-control intraabdominal and pelvic bleeding. More providers are being trained in the use of REBOA. It may become more commonly used in the future to prolong the “golden hour” in patients with significant intraabdominal and pelvic hemorrhage.

TISSUE CLAMPS

Another novel tool for hemorrhage control is a proprietary tissue-clamping tool called the iTClamp (Innovative Trauma Care Inc., San Antonio, TX). The device contains eight small needles that are inserted into the skin on opposite sides of the wound and tightened together by pushing together the top of the device (**Figure 137-17**). The iTClamp can be used to tightly approximate the edges of wounds unable to be controlled by direct pressure. Pressure from the device will tamponade the bleeding. Recent case reports performed in trauma patients showed that the iTClamp was successfully able to tamponade penetrating neck wounds with minimal discomfort.⁶⁶ The application of the iTClamp allowed patients to be safely transferred to the computed tomography scanner and subsequently to the Operating Room. Another study used cadaveric hemorrhage models to evaluate the efficacy of the iTClamp for hemorrhage control.⁶⁷ Use of the iTClamp reduced fluid loss in any wound, resulted in no alteration in fluid losses with or without movement of the patient, and did not occlude distal arterial blood flow.⁶⁷

FIGURE 137-17. The iTClamp. (Courtesy of Innovative Trauma Care Inc., San Antonio, TX.)

FIGURE 137-18. The Xstat. (Courtesy of RevMedX Inc., Wilsonville, OR.)

WOUND CLOSURE VERSUS PACKING

The wound can be approximated, a pressure dressing applied, and the limb elevated when oozing cannot be controlled by any other method. Alternatively, the wound can be packed with saline-moistened gauze until better hemostasis is achieved. **Apply as much packing into the wound as possible and then pack some more.** Obtain a coagulation profile in anyone with persistent diffuse bleeding. The wound can be approximated after the coagulopathy is corrected if a correctable coagulopathy is identified.

Xstat can be used for all wounds (RevMedX Inc., Wilsonville, OR).⁶⁸ It is meant to be used on life-threatening junctional wounds not amenable to standard tourniquets. It should not be used in the abdomen, pelvis, or thorax. It looks like a big syringe filled with pellets (Figure 137-18). It contains 92 compressed cellulose sponges coated with a shellfish extract. The Xstat is for single use and may be used for up to 4 hours for bleeding control. Place the applicator in the wound and depress the plunger to fill the wound with the pellets. The number of pellets to inject will vary with the size of the wound. Up to three applicators may be used on large wounds. The sponges will rapidly expand to tamponade the bleeding. Cover the wound with a compression dressing. Remove the sponges after the bleeding has stopped. Each sponge contains a radiopaque marker for easy radiograph detection.

ALTERNATIVE TECHNIQUES

The general techniques discussed above apply to bleeding from most sites. There are techniques of hemorrhage control applicable to specific anatomic sites.

THE HAND

Hand injuries pose special problems. Strict hemostasis is necessary to examine the wound and identify any associated damage to joint capsules, nerves, and tendons. Place a tourniquet to exsanguinate the extremity and facilitate wound inspection. Elevate the limb and wrap it with an elastic bandage to “milk” the venous return toward the heart. Apply a blood pressure cuff to the forearm or arm and inflate it above the systolic blood pressure. This prevents arterial inflow while minimizing the backflow from venous engorgement to reliably provide a bloodless field.

A digital tourniquet may expedite the examination if the injury is confined to a single digit.^{69,70} A Penrose drain can be wrapped about the base of the finger and secured with a hemostat (Figures 129-3 and 137-19A). Mark a 0.25 inch Penrose drain with two lines placed 26 mm apart. Stretch the Penrose drain about the base of an average adult finger until the lines meet. Clamp the Penrose drain with a hemostat to generate a sufficient but safe pressure.⁶⁹ An alternative

FIGURE 137-19. Finger tourniquets. **A.** A Penrose drain wrapped about the base of the finger provides effective hemostasis. **B.** A finger of a surgical glove has been cut and rolled down the finger. **C.** A commercial finger tourniquet.

is to use a surgical glove with the fingertip cut off and rolled down to leave a tight band at the base of the digit (Figures 129-4 and 137-19B). Use a glove size larger than what would typically fit the patient for general use to avoid generating excessive pressure.⁶⁹ Disposable, preformed, rubber digital tourniquets are commercially available (Figures 129-5, 129-6, and 137-19C).⁷¹ Refer to Chapter 129 for a more complete discussion of digital tourniquets. These tourniquets exsanguinate the digit and prevent arterial inflow. **Do not apply digital tourniquets for more than 20 to 30 minutes to avoid injury to the digital nerves.**

Hemostasis is important but should not be pursued without regard to the surrounding tissues. **Do not blindly probe hand wounds deep to surface structures. Blind exploration or clamping is never advised.** Probing and clamping can damage small nerves and other structures. **Do not use vasoconstrictors (e.g., epinephrine) on the digits.** Consult a Hand Surgeon if wounds require deep exploration, a digital artery is injured, or hemostasis is difficult to achieve.

THE SCALP

Scalp wounds frequently occur in association with other major injuries. Control of scalp bleeding is frequently not the priority in the multiple trauma patient. Continued brisk bleeding from the scalp can contribute to hemorrhagic shock.⁷² Techniques for vascular control of the damaged scalp should be simple, fast, and not interfere with the ongoing assessment and treatment of other injuries.

A few techniques can help gain rapid control of scalp bleeding with a minimal investment of time or personnel (Figure 137-20).

FIGURE 137-20. Hemorrhage from scalp wounds can easily be controlled. **A.** Hemostatic Raney scalp clips seal the wound edge. **B.** Hemostats applied about the edge of the wound. **C.** A Penrose drain wrapped about the head.

The fastest and most effective method is the application of Raney scalp clips (**Figure 137-20A**). These have been used for years by Neurosurgeons performing craniotomies.⁷³ **Use scalp clips on the thick skin of the scalp. Use elsewhere can crush and devitalize thin skin or damage subcutaneous structures.** Apply hemostats at the wound edges if scalp clips are not available and where the bleeding is brisk (**Figure 137-20B**). Inject local anesthetic solution with epinephrine into the wound edges to constrict smaller vessels. A Penrose drain can be wrapped about the head as a temporary tourniquet (**Figure 137-20C**).¹³ Figure-of-eight sutures, simple running sutures, mattress sutures, or surgical staples temporarily close a scalp wound and achieve hemostasis. A more definitive closure can be performed after the patient has been stabilized. Use one or more iTClamps to stop scalp bleeding (**Figure 137-17**).

The use of Raney clips can be cumbersome. This is especially true if the Emergency Physician has little or no experience with the system. It requires a special applicator, individually loading the clips on the applicator, and manipulating the clips. A much simpler system is a Raney clip gun (**Figure 137-21**). The clips are preloaded in a magazine that snaps into the clip gun. A clip is applied by touching the tip of the gun to the scalp edge and squeezing the handle. The clip gun then ejects and applies a clip, loads the next clip, and is set to apply the next clip. The process and technique of applying a clip is like using a skin stapler. The clip gun is much easier, quicker, and simpler to use than the traditional method.

MAJOR EXTREMITY INJURY

Amputations, major crush wounds, soft tissue avulsions, and fractures of the extremity may present with active bleeding. Diffuse bleeding from muscle and soft tissue may be difficult to localize and treat. Immobilize the extremity and apply direct pressure if discrete bleeding sites cannot be identified. Reduction of long bone fractures and immobilization of soft tissue injuries can stabilize the damaged tissue and minimize blood loss. The application of a MAST suit (Chapter 230) or air splint may stabilize bony fragments and tamponade active bleeding.⁷⁴ Consider the application of a topical

FIGURE 137-21. The Medtronic Clip Gun Kit (Medtronic Neurosurgery, Goleta, CA). It contains the clip gun, three magazines preloaded with Raney-type clips, a clip remover tool, and an instruction manual.

hemostatic agent such as Hemcon ChitoGauze or Quikclot Combat Gauze. These conservative and simple measures can dramatically reduce ongoing blood loss.

EXPOSED BONE

Exposed bone tends to ooze. This can be especially troublesome in amputations and crush wounds. Bone wax can tamponade these sites and temporarily halt the bleeding until more definitive action can be taken. Open a sterile package of bone wax and hold it in a sterile-gloved hand to warm it up and make it more pliable. Remove a piece of the bone wax and mold it over the end of the broken bone. Firmly push the bone wax into the bone to seal the edges. **Use care to prevent lacerating the glove and finger, resulting in a potentially significant bloodborne pathogen exposure.** Possible complications associated with the use of bone wax include granulomatous reactions, infection, and interference with osteogenesis. An alternative to bone wax is Ostene (Baxter Healthcare Corp., Los Angeles, CA), a water-soluble alkylene oxide copolymer that dissolves within 24 hours.

ARTERIAL INJURIES

Puncture wounds, open fractures, amputations, and deep lacerations may be complicated by arterial injuries. These may be obvious if they present with dramatic pulsatile bleeding. The elastic recoil of arteries frequently causes the damaged vessel to retract deep within the wound and rebleed later after wound closure. Recurrent pulsatile bleeding and deep hematoma formation are characteristics of unrecognized arterial injuries. This is particularly true of puncture wounds where the damage may be deep and not visible to the examiner's eye. These wounds may require angiography, embolization, or wound exploration to identify the source if they rebleed despite local measures.

ASSESSMENT

The ideal goal in wound care is to achieve a dry bloodless field without compromising the vitality of the tissue. Simply controlling the hemorrhage and preserving life is the goal in major trauma victims. Expediting wound closure and preventing hematoma formation is a more modest goal for minor injuries.

AFTERCARE

A healthy wound is proof of adequate hemostasis. Routine wound care should verify a healthy incision line and the absence of a hematoma or an infection. Many of the novel hemostatic agents may present unique challenges in wound care after their application, as many are hard to remove from the wound bed. Refer to Chapters 114 through 119 regarding the details of wound care and repair. Update the patient's tetanus immune status as required.

COMPLICATIONS

The techniques in this chapter are all safe and effective when used as described. Complications occur when the described techniques are used in excess or in the wrong setting. The specific complications of each technique are discussed under each specific section in this chapter.

FUTURE CONSIDERATIONS

The area of hemostasis is very active in terms of research and development. Injectable foam can be used in the abdomen.⁷⁵⁻⁷⁷ It is injected into the abdomen and expands to fill all the areas and tamponade the bleeding. It may be developed to work on extremity wounds. Polystat is a synthetic polymer that is injected into a vein. It seeks out clots and binds to them, making them stronger and longer lasting. Remedium Technologies is developing a foam to clump blood cells and reduce external hemorrhage. Gel-e is a biopolymer that is biocompatible and form fits to external hemorrhage. It creates rapid coagulation, is durable, and has antibacterial properties. AC5 is a synthetic peptide made of amino acids that is sprayed onto a wound and intercalates with connective tissue to form a lattice-like gel. Hemospray is a powder spray being tested for lower and upper gastrointestinal bleeding.⁷⁸ Hydrogels are being developed.⁷⁹ These agents are not ready as yet for use in the Emergency Department but have promise.

SUMMARY

There are numerous techniques available for the control of hemorrhage. A methodical approach to the bleeding wound will optimize the outcome. Use simple measures first and take progressive systematic steps until hemostasis is achieved. All bleeding eventually stops! The goal is to halt the bleeding before irreparable harm occurs.

Trigger Point Injections

Danielle Campagne

INTRODUCTION

Musculoskeletal pain is a significant health problem for the North American population.¹⁻⁹ Such pain affects between 10% and 20% of the population and is a major cause of morbidity.¹ It is estimated that approximately half of chronic pain complaints result from a musculoskeletal origin.² Myofascial trigger point (MTrP) injections may alleviate much of this pain.¹⁰⁻¹³ It is imperative that the Emergency Physician perform a thorough history and physical examination with an emphasis on the neurologic and orthopedic examination to exclude other causes of musculoskeletal pain.³ The performance of MTrP injections by Emergency Physicians is underused.^{14,15}

ANATOMY AND PATHOPHYSIOLOGY

The etiology and pathogenesis of MTrPs have yet to be elucidated. The precise mechanism by which MTrP injections inactivate the trigger point is unknown. Researchers agree that acute trauma or repetitive microtrauma appears to lead to the development of a MTrP.⁶ The risk for a MTrP is increased when other factors are present (e.g., poor physical conditioning, poor posture, and prolonged bending).⁷ MTrPs mostly affect the muscle groups used to maintain posture (i.e., muscles of the neck, shoulders, and back). The patient may present with a tension headache or temporomandibular joint pain when the head and neck regions are affected.⁶

MTrPs are hyperirritable points located within a taut band of skeletal muscle or fascia.² When compressed, these points may

cause autonomic pain and local tenderness.² Pain may be diffuse if not localized to the MTrP. The pain can be described as burning, dull, sharp, or some combination of these. Autonomic changes associated with a MTrP include dizziness, edema at the site, lacrimation, piloerection, salivation, and tinnitus. The compression of a MTrP can further lead to muscle spasm, stiffness, shortening, and fatigue.¹ This may progress to impaired muscle coordination, reduced muscle strength, and decreased range of motion.¹

DIAGNOSIS OF MTrPs

The diagnosis of a MTrP relies on the criteria of a tender spot with an underlying taut band, pain on palpation of the tender spot, and a local twitch response (i.e., a transient local contraction of skeletal muscle fibers in response to palpation or needling).^{3,10} The data on clinical outcomes provide no definitive answer. The best outcomes appear to occur in patients who exhibit a local twitch response with palpation.⁴ The current literature provides no pathophysiologic explanation for this result. There are no laboratory, pathology, or radiology studies to identify or verify a MTrP.

Identifying the palpable, taut band is critical in locating the MTrP (Figure 138-1). The MTrP can be identified by flat palpation, snapping palpation, pincer palpation, and/or deep palpation. Flat palpation uses a fingertip to slide across the skin over the affected muscle to find the MTrP (Figure 138-2). The taut band may be felt under the

sliding fingertip. Snapping palpation uses the tip of the index finger to pluck the skin to feel the underlying taut band. This motion is similar to plucking a guitar string. Pincer palpation uses the dominant thumb and index finger to firmly grasp the skin and muscle as a unit and roll it to identify the taut band (Figure 138-3). Deep palpation can be used to identify a deep MTrP or a superficial MTrP in an obese patient. Use the tip of the index finger to press slowly and deeply to reproduce the patient's symptoms and identify the MTrP.

Studies have used a variety of injectant fluids and solutions during injection of MTrPs (e.g., botulinum toxin, corticosteroid suspensions, ketorolac, local anesthetic solutions, sterile saline, and sterile water).^{1,16-18} **No specific fluid or solution has demonstrated a clearly superior clinical outcome.** The optimal injectant fluid or solution varies by Physician preference. The duration of pain relief has been found to last longer than the duration of action of the injectant. A meta-analysis of eight randomized controlled clinical trials examined the type of injectant used and the resulting effect on symptom relief.¹ The authors concluded that the injection of either lidocaine or botulinum toxin provided greater symptom relief than placebo (i.e., dry needling alone). A Cochrane analysis looked at four studies totaling 233 patients that evaluated botulinum toxin A as the injectant versus placebo.¹⁷ It concluded there was inconclusive evidence to support the use of botulinum toxin A in MTrP. **No injectant was more efficacious than any other injectant.** Another study looked at pain relief with an injection of lidocaine versus

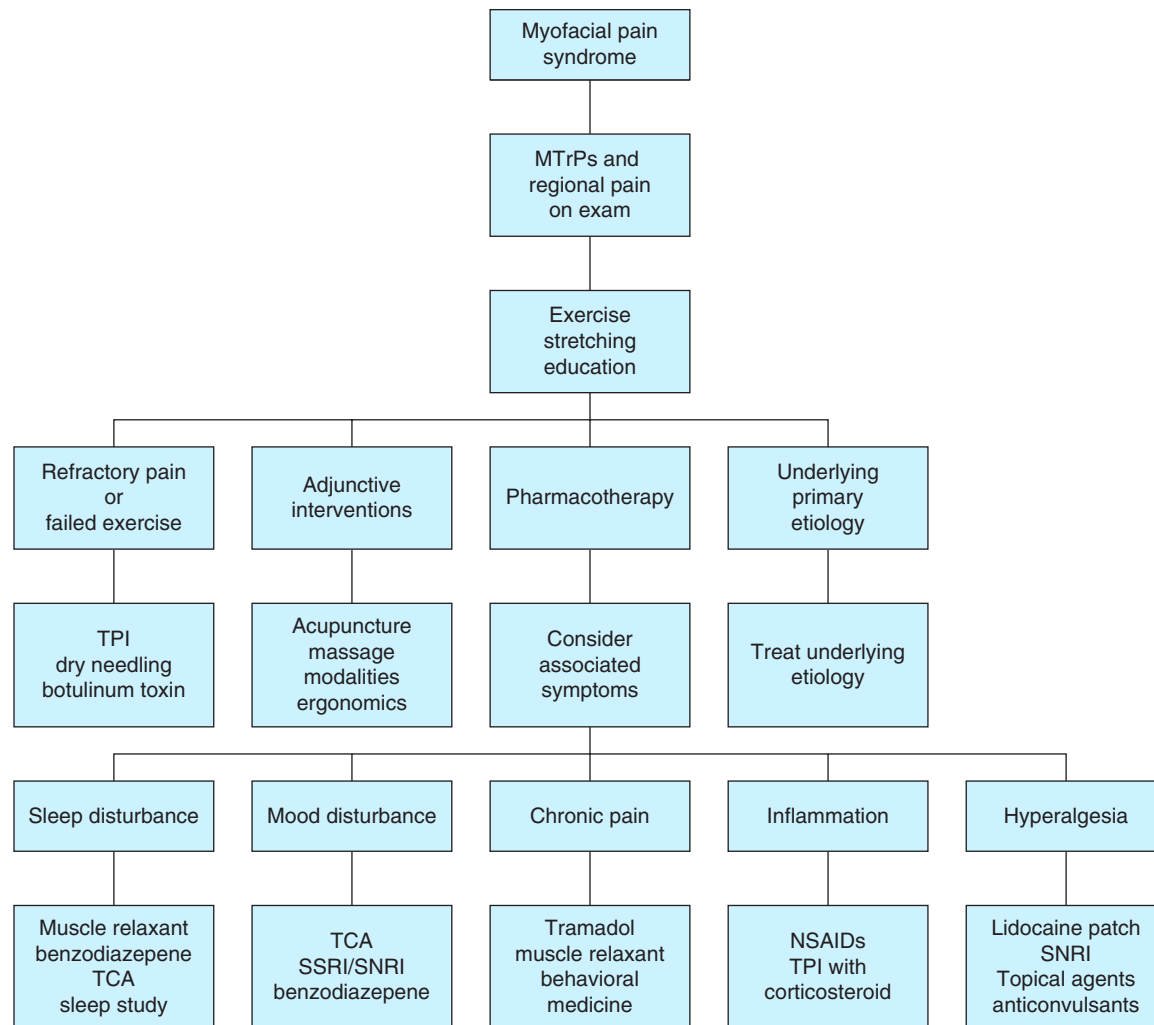

FIGURE 138-1. MTrP treatments. NSAID, nonsteroidal anti-inflammatory drug; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; TPI, trigger point injection. (Used with permission from reference 10.)

FIGURE 138-2. Flat palpation to identify a MTrP or taut band. **A.** The index finger pushes down over the MTrP or taut band. **B.** The index finger rolls off the tender spot and pushes the skin to one side. **C.** The index finger pushes the skin back to the tender spot to feel the taut band. **D.** The index finger rolls off the tender spot and pushes the skin to the opposite side.

physical therapy versus both modalities (i.e., MTrP lidocaine injection and physical therapy) combined.¹⁸ The study showed no difference between the three groups. Pain was relieved in all groups. This finding is consistent with the general medical literature on the topic which is still in its infancy and provides no clear indication of effectiveness. More research is required in this area.

NONINVASIVE MTrP MANAGEMENT

Numerous noninvasive techniques have been used to treat MTrPs (**Figure 138-1**).^{2,5,8,10,11,19-21} One of the more common techniques uses spray vapocoolant (e.g., ethyl chloride) in combination with passive muscle stretch to relax the taut band. Ischemic compression therapy is the application of pressure to the MTrP to produce ischemia and ablate the MTrP. Digital pressure is applied and increased until the taut band relaxes. A deep pressure or stroking massage can be used to stretch the affected muscle and relax the taut band. Physical therapy can stretch and relax the affected muscles. Transcutaneous electrical stimulation units with the electrodes placed over the MTrP can be used to stimulate and relax the underlying muscle. Ultrasound can transmit heat and vibration to a superficial MTrP with the goal of muscle relaxation.

Some apply massage followed by an injection. The application of pressure to the MTrP is considered critical in the treatment. Warn the patient what to expect when you apply pressure to the MTrP. Apply pressure over the point of maximal tenderness with both thumbs. An elbow or forearm can apply pressure to larger areas. Hold the pressure until the underlying MTrP relaxes and goes away. It usually takes 2 to 4 minutes of pressure to relieve the pain. Inject the MTrP and reapply pressure.

INDICATIONS

MTrP injections have been advocated for points of muscle pain that are not assisted by noninvasive therapy (e.g., ischemic compression therapy, massage, physical therapy, spray vapocoolant, transcutaneous

FIGURE 138-3. Pincer palpation to identify a MTrP or taut band. **A.** The skin, subcutaneous tissue, and muscle are grasped between the thumb and index finger. **B.** The fingers are moved back and forth (arrows) to feel the taut band as it is rolled between the fingertips.

electrical stimulation, and ultrasound) (**Figure 138-1**).^{8,10} There is no emergent indication for a MTrP injection in the Emergency Department.

CONTRAINDICATIONS

Contraindications to MTrP injections are similar to other injection procedures (e.g., anticoagulation therapy, a bleeding disorder, a dermatologic condition, a local or systemic infection, or malignancy over the injection site).⁵ The traditional teaching of anticoagulation therapy being a hard contraindication to any invasive pain procedure (including a MTrP) is being challenged in the literature. A study looked at invasive pain procedures in 4766 patients and found no complications associated with it. Patients who stopped anticoagulation to receive the procedure had more serious complications (e.g., stroke and death).²² Relative contraindications include allergies to local anesthetic agents, patients with needle phobias, and uncooperative patients.

It is important to differentiate between a patient with one or more isolated MTrPs and fibromyalgia (**Table 138-1**). **A patient with fibromyalgia can have multiple MTrPs. Do not perform MTrP injections in a patient with fibromyalgia.** The injection may worsen their pain.

EQUIPMENT

- Sterile gloves
- Sterile skin marking pen
- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Sterile gloves
- Gauze 4×4 squares
- 25 or 27 gauge, 1.5 inch needle for superficial trigger points
- 25 or 27 gauge, 2 inch needle for deeper trigger points
- 3 or 5 mL syringe
- Injection solutions

TABLE 138-1 Determining Isolated MTrPs Versus MTrPs Associated with Fibromyalgia		
Characteristic	Isolated MTrPs	Fibromyalgia
Immediate response to injection therapy	Resolution of symptoms	Poor or none
MTrPs	Few, discrete, and localized	Many and widespread
Muscle tissue	Taut bands palpable	Soft, no taut bands palpable
Muscle range of motion	Stiff and decreased	Normal
Pain and tenderness	Local or regional	Generalized and widespread
Sexual predilection	None	Female

Source: Modified from reference 2.

- ▶ Lidocaine without epinephrine
- ▶ Bupivacaine without epinephrine
- ▶ Sterile water
- ▶ Sterile normal saline
- ▶ Botulinum toxin A, 20 units or 0.4 mL (50 U/mL) (Botox; Allergan, Irvine, CA) diluted to 1 mL with normal saline
- Ultrasound machine with a 5 to 7.5 MHz probe
- Ultrasound gel

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Place the patient in a comfortable position on a gurney with the MTrP(s) exposed. The muscle with the MTrP(s) is ideally positioned so that it is relaxed. Identify the MTrP site(s). Clean the skin of any dirt and debris. Use ultrasound to ensure there are no neurologic, tendinous, or vascular structures in the area that can be injured by the MTrP injection. Mark the MTrP skin site with a pen. Apply povidone iodine or chlorhexidine solution over the injection site(s) and surrounding skin and allow it to dry. Follow aseptic technique for the injection procedure.

Prepare multiple 3 or 5 mL syringes armed with a 25 or 27 gauge needle and containing the injection solution. The editor recommends local anesthetic solution as the injectant in the Emergency Department. The number of syringes to prepare depends upon the number of MTrP sites to be injected and the volume injected at each site.

TECHNIQUES

INJECTION TECHNIQUE

Reidentify the MTrP site. Warn the patient what to expect (i.e., exacerbation of their symptoms which is usually pain) upon the injection. Use the nondominant index and middle fingers to locate and isolate the MTrP or taut band (**Figures 138-4A and 138-4B**). Insert the needle into the skin approximately 1 cm away from the MTrP or taut band, at a 30° angle to the skin, and aimed at the MTrP or taut band. Advance the needle into the MTrP or taut band. **Insert the needle briskly and in a controlled manner.** Use a “fast in, fast out” approach to elicit a local twitch response when the tip of the needle hits the MTrP or taut band.⁸ **Aspirate to ensure that the tip of the needle is not within a blood vessel.** Inject the solution within the syringe.

FIGURE 138-5. Injection of the MTrP or taut band. The needle is inserted through a single skin puncture and into multiple places within the MTrP or taut band in a fanlike pattern.

Common practice is to inject between 0.5 and 2.0 mL total per MTrP.⁵ This volume can be injected into the one location of maximal tenderness or numerous sites in a fanlike pattern within the MTrP (**Figure 138-5**).⁹ Withdraw the needle to the skin surface once the injection is completed but do not completely remove it from the skin. Allow the injection solution to work for up to a minute. Reinsert the needle into the MTrP in a fanlike pattern until the local twitch response is no longer elicited or resisting muscle tautness is no longer palpable.⁷ Completely withdraw the needle. Apply pressure over the injection site to prevent bleeding and hematoma formation. Instruct the patient to slowly and fully stretch the affected muscle group.⁸

DRY NEEDLING

The technique of dry needling involves inserting a needle into multiple sites within the MTrP or taut band without injecting any fluid or solution.²³⁻²⁷ This is similar to acupuncture. Insert the needle as described above. Withdraw the needle until the tip is just below the

FIGURE 138-4. Identifying and injecting the MTrP or taut band. **A.** Push with the index finger and middle finger, alternating between the fingers, to identify and isolate the MTrP or taut band. **B.** Compress the skin with both fingers to secure the MTrP or taut band and inject it.

skin surface. Redirect and reinsert the needle in a fanlike pattern into a different location within the MTrP or taut band. Continue this process several times until the local twitch response is no longer elicited or resisting muscle tautness is no longer palpable.⁷ Completely withdraw the needle. Apply pressure over the injection site to prevent bleeding and hematoma formation. Instruct the patient to slowly and fully stretch the affected muscle group.⁸

ASSESSMENT

The patient should experience relief of their symptoms after the injection, especially if a local anesthetic was injected. The injection of a MTrP breaks the pain cycle. Passively and actively stretch the affected muscle in a slow manner to stretch it out. Apply digital compression to the injection site, the MTrP, and the taut band. Repeat the procedure with local anesthetic solution or by dry needling if symptoms are still present. Observe the injection site and apply pressure to control any bleeding.

AFTERCARE

Apply a simple adhesive bandage over the injection site. Postinjection soreness is expected and can be managed with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). Warn the patient that the pain often comes back but is less intense. Encourage the patient to use the affected muscle through its full range of motion but avoid strenuous activity for 1 to 3 days after the injection. Instruct the patient to return to the Emergency Department immediately if they develop fever, chills, swelling at the injection site, redness at the injection site, or any drainage from the injection site.

COMPLICATIONS

The complications are the same as any injection procedure (e.g., infections and needle breakage). An allergic reaction to the injection fluid or solution is possible. Treat this as any other allergic reaction. A thorough history may prevent an allergic reaction to the injectant. Never aim the needle at an intercostal space to prevent an iatrogenic pneumothorax.⁷ Hematoma formation following injection can be minimized with proper technique and the application of pressure over the soft tissue after the needle is withdrawn.² Never inject the patient when they are standing or sitting in a chair. Ensure that the patient is always on a gurney and the side rails are upright to prevent injury if the patient becomes vasovagal or experiences syncope. Injury and inadvertent injection to adjacent structures can be avoided by knowing the local anatomy and using ultrasonography before the injection to identify adjacent structures.

SUMMARY

MTrP injections and nonpharmacologic management can be performed in the Emergency Department (**Figure 138-1**). They are simple, quick, and effective to manage a patient's pain. The efficacy of MTrP injections have not yet been established. MTrP injections serve as part of a treatment plan to offer quick relief of myofascial pain when other noninvasive therapies have been unsuccessful or when opioids are contraindicated. The current opioid epidemic that is occurring worldwide may result in more Emergency Physicians performing injection of MTrPs in patients.

Escharotomy

Michael A. Schindlbeck and Carlos E. Brown, Jr.

INTRODUCTION

Few injuries have the same capacity for physical destruction and emotional devastation as do thermal burns. They are relatively common presentations that often require resource-intensive management. The preceding decade saw nearly 500,000 burn injuries per year receiving medical care in the United States.¹⁻³ Over 40,000 of these patients required inpatient treatment for their injuries and up to 73% of these injuries occur at home. The associated expenses are staggering. The mean hospital stay was over 1 week and at an average cost over \$50,000 per admission. An average of over 4500 individuals per year died from burn-related injuries. Fires and burns represent the fifth, third, sixth, and eighth leading causes of unintentional injury deaths in the United States for the age groups of 1 to 4 years, 5 to 9 years, 10 to 14 years, and ≥ 65 years, respectively.¹ Less than 6% of the above patients who were admitted to a recognized burn center subsequently died from their injuries.²⁻⁴ **These data underscore the need for rapid and effective emergency care focused on facilitating the successful transfer of these patients to specialized burn centers.** The initial management of these patients invariably falls upon the Emergency Department. The Emergency Physician needs to be well versed in the recognition of acute thermal injuries, their associated complications, and their appropriate treatment.

Thermal injuries have the potential to affect any body surface, both internally and externally, with which a heated medium comes into contact. The overall depth and degree of injury is multifactorial. It is typically proportional to the temperature of the source medium, its unique specific heat, the actual rate of energy transfer, and the overall duration of tissue exposure. This chapter focuses on the skin and its response to burn injuries.

ANATOMY AND PATHOPHYSIOLOGY

Skin exposure to any significant heat source results in a spectrum of pathophysiologic responses. An initial coagulation necrosis occurs as thermal energy is transmitted directly into living tissue. These cells subsequently die and lyse, spilling their intracellular contents and increasing the surrounding interstitial oncotic pressure. These processes serve to trigger a secondary edematous reaction in the surrounding tissues. Cellular breakdown releases a host of generalized inflammatory markers (e.g., histamines, prostaglandins, cytokines, and interleukins). These agents further exacerbate the localized edematous reaction via vasodilation and increased capillary permeability.⁵

Burns involving over 20% of a patient's total body surface area (TBSA) can result in secondary injury extending beyond the locally involved tissues. The inflammatory outburst can become significantly large enough to produce a systemic pathophysiologic response of internal fluid shifts and external fluid losses. Inadequate fluid resuscitation can result in tissue hypoperfusion and multisystem organ dysfunction. A secondary systemic inflammatory response syndrome (SIRS) can further complicate the clinical course of patients whose burns involve greater than 30% TBSA. This frequently results in widespread intravascular hemolysis, acute renal failure, and acute lung injury.^{6,7} A global hypermetabolic state tends to accompany these injuries. Secondary catecholamine release can raise the resting metabolic rate approximately two to three times above baseline when greater than 30% to 40% of a patient's TBSA is involved. The consequent catabolic tissue breakdown further

FIGURE 139-1. The depth of burn wounds. (Used with permission from Schafermeyer R, et al: *Strange and Schafermeyer's Pediatric Emergency Medicine*, 4th ed. New York: McGraw-Hill; 2015.)

exacerbates the emerging multisystem organ dysfunction.^{5,8} These burns are associated with significant morbidity and mortality. Survivability rates are indirectly proportional to the TBSA involved. Of special note is the loss of a protective functioning epidermis as severe and overwhelming infection becomes a significant potential complication in those who survive beyond the initial resuscitative period.⁹ Systemic organ failure from the "burn sepsis" continues to be a leading cause of death in these individuals.

Burns are classified based on the overall depth of injury sustained. First-degree burns are limited solely to the epidermal layer (Figure 139-1). They typically present as a tender erythematous region of skin. This redness arises as the underlying dermal capillaries dilate in response to the overlying injury. Deeper tissues are not directly involved and the capillary walls remain intact. This explains the blanchable nature of these burns on physical examination. Blistering of the skin indicates involvement of the underlying dermis and is not seen with first-degree burns. Classic examples of first-degree burns include flash burns and sunburns. These burns do not generally illicit the systemic pathophysiologic response described above despite extensive surface area involvement. **Do not include first-degree burns when calculating the overall TBSA affected.**

Second-degree burns are the partial thickness injuries. These burns extend into but not through the dermis (Figure 139-1). They are subdivided into superficial second-degree and deep second-degree burns. Superficial second-degree burns are typically moist to the touch, pink to reddish in color, blanchable with gentle pressure, and covered with tensely distended blisters. Cutaneous nerves, located in the uninvolved underlying deeper dermal layer, remain viable, bestowing an exquisitely painful character to these burns. Deep second-degree burns involve the deeper reticular dermis and differ noticeably in appearance. They tend to be drier in texture and have a more blanched whitish complexion. These injuries tend to be less painful than their superficial counterparts due to destruction of the cutaneous nerves.

Full-thickness burns involve the destruction of the entire epidermal and dermal tissues and are classified as third-degree burns (Figure 139-1). Coagulation necrosis imparts a dry leathery appearance to these burns. The overlying tissue is insensate secondary to the obliteration of the cutaneous nerves. The dermal proteins in third-degree burns are heated and tend to contract, facilitating the formation of a constrictive eschar of scar tissue. Rare scenarios where the tissue destruction extends through the dermis and into the underlying tissues (e.g., muscle, bone, and fascia) are categorized as fourth-degree burns. These injuries are catastrophic in appearance and tend to result in extensive tissue loss.¹⁰

Burn injuries can generate an extensive redistribution of fluids into the interstitial spaces. Aggressive fluid resuscitation will help

to limit the consequent invariable hypoperfusion but does nothing to limit further leakage of fluids into the interstitium. This third spacing can lead to significant elevations in the localized hydrostatic pressures in tissues already constricted by an extensive overlying eschar. Impairment in regional lymphatic and venous drainage further exacerbates this adulteration of the local pressure gradient. The normal arteriolar perfusion pressure will be eventually overwhelmed and result in distal tissue hypoperfusion. Distal tissue necrosis can progress to limb loss if the burn occurs on an extremity. Swelling and scarring can result in the loss of a functional airway if the burn occurs over the neck. Burns occurring across the torso can produce an abdominal compartment syndrome, progressing to intraabdominal organ ischemia, impaired diaphragmatic excursion, and reduced cardiac output secondary to diminished venous return.¹¹⁻¹³ Significant thoracic burns can impede the dynamic chest wall motions of respiration producing a further restrictive ventilation that can progress to respiratory failure.¹⁴

INDICATIONS

The general indication to perform an escharotomy is to limit the circulatory or respiratory insult caused by an overlying circumferential burn. These indications can be present with a significant noncircumferential burn. The development of a significant restrictive physiology often requires several hours after the initial burn.¹⁵ Most patients could be successfully transported to a specialized burn center within this time span. Invasive means to assess compartmental pressures (Chapter 93) should not be undertaken at the expense of proper fluid resuscitation and preparation for transport. The Emergency Physician must maintain a high index of suspicion to limit any further injury to viable tissues. **An escharotomy should be performed without delay once the decision is made to perform an escharotomy.** Perform the escharotomy in consultation with the accepting burn center and/or Burn Surgeon if possible and time permits.

Any signs and symptoms of limb hypoperfusion should be taken seriously. **A restrictive etiology should be considered only if hypoperfusion persists despite adequate volume resuscitation as hypovolemia is the most likely etiology of impaired tissue perfusion immediately after the burn injury.** Perform and document frequent and repeat physical examinations including an assessment of overall skin appearance, distal capillary refill, peripheral pulse checks, any motor deficits, and any sensory deficits. **Depending on the presence of palpable pulses as the sole means to approximate compartmental pressures will grossly underestimate the need for decompression.**¹⁶

Several methods are available to aid the Emergency Physician in frequently assessing for tissue hypoperfusion. Bedside arterial Doppler provides an easy means to gauge peripheral perfusion. It is concerning if any signs of a progressive reduction in arterial flow occur. The absence of arterial flow on a bedside Doppler is an indication for emergent escharotomy. **Keep in mind that the presence of Doppler pulses does not necessarily indicate adequate perfusion.** Pulse oximetry provides another useful adjunct. A distal oxygen saturation of less than 95% in a circumferentially burned extremity has been shown to be an indicator for an emergent escharotomy.¹⁷ Compartmental pressures can usually be measured quickly at the bedside (Chapter 93). An intracompartmental pressure of ≥ 40 mmHg is an indication for an escharotomy. Consider an escharotomy for intracompartmental pressures between 25 and 40 mmHg.

Significant burns to both the chest and abdomen can result in restricting ventilation. Respiratory distress is generally multifactorial in burn patients. A concurrent inhalation injury or secondary acute respiratory distress syndrome should be entertained in the

differential diagnosis. **Early intubation and mechanical ventilation is essential in any burn patient exhibiting respiratory distress.** Mechanically ventilated patients with severe truncal burns, persistent arterial hypercapnia, and elevated peak inspiratory pressures (although often confounded by concurrent airway edema and secondary bronchospasm) are objective signs suggesting a significant restrictive respiratory physiology. An emergent escharotomy could be a lifesaving procedure.

Facial burns can result in eschar formation around the eyes and mouth. Measure intraocular pressure if an eschar surrounds the eye. Elevated intraocular pressure (Chapter 188) should be decompressed with a lateral canthotomy (Chapter 194).

CONTRAINDICATIONS

No specific contraindications exist for performing an escharotomy provided the above indications are satisfied. The concern for possible medical futility in patients with no chance of salvageability is very difficult to determine in the Emergency Department.

EQUIPMENT

- Sterile gloves and gown
- Face mask with an eye shield or eye protection
- Hat
- Povidone iodine or chlorhexidine solution
- #10 scalpel blade on a handle
- Electrocautery unit, optional but highly recommended
- Gauze 4×4 squares
- Local anesthetic solution
- Needles and syringes
- Suture to tie bleeding vessels
- Procedural sedation medications and supplies (Chapter 159)

PATIENT PREPARATION

This procedure is considered life and/or limb sparing. Inform the patient and/or their representative for the need to perform an escharotomy, its risks and benefits, and the outcome if not performed. Document the discussion in the medical record. The patient's medical condition often precludes them from signing a consent form. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Escharotomies are performed on tissues previously destroyed by full-thickness burns. Some intermittent nerve function can persist. This may necessitate the use of local anesthesia and/or procedural sedation (Chapter 159). Administer some form of procedural sedation (Chapter 159) in the conscious patient for pain control and to limit the profound anxiety elicited by this procedure. **Strict aseptic technique should be followed.** Clean the skin of any dirt or debris. Apply dilute povidone iodine or chlorhexidine solution to the skin and allow it to dry. **This procedure has the potential to introduce a devastating infection.**

TECHNIQUES

Make the skin incisions along the proper plane with a #10 scalpel blade or an electrocautery unit. Electrocautery has the added ability to coagulate the potential bleeding encountered from inadvertently incised superficial subcutaneous vessels (**Figure 139-2A**). **Limit the**

A

B

depth of the incision to the dermis. Use extreme caution to avoid overaggressively extending these incisions too deeply and injuring the underlying deep investing fascia, muscles, and/or tendons. There is a pressure buildup underlying the constricting tissue. **A properly placed incision should elicit a rapid separation of the eschar exposing the underlying subcutaneous fat.** Carefully run a gloved fingertip along the incision lines to detect any residual connecting bands of tissue requiring further incision. To ensure an adequate release, continue the incision across the entire eschar and extending 1 to 2 cm into the unscarred tissue on either end. Cosmetic concerns are not a concern as the incised tissue will often require eventual skin grafting if the patient survives.

FACE ESCHAROTOMY

The face is commonly involved in burn injuries. Eschars can form on the face just as they can form on other areas of the body. A patient complaint of any visual disturbance or burns around the eye requires a thorough investigation. This includes measuring visual acuity, a topical fluorescein examination, a fundoscopic examination, and measurement of intraocular pressure (Chapters 185 and 188). Elevated intraocular pressure may require a decompressive lateral canthotomy and cantholysis (Chapter 194).

Perioral burns can form eschars. These eschars may limit or prevent mouth opening. An escharotomy may be required to aid in oropharyngeal suctioning and orotracheal intubation. Make the

FIGURE 139-3. The location of incisions for escharotomies. **A.** The head and neck. **B.** The extremities and torso. **C.** The hand and fingers.

escharotomy incisions at the bilateral corners of the mouth and extending directly posterior (in the supine patient) and approximately 4 to 5 cm long (Figure 139-3A). **Make the incisions very superficial to prevent injury to the underlying facial artery, cranial nerves, superficial facial structures, and parotid gland.**

NECK ESCHAROTOMY

Significant burns to the neck can result in the formation of a constrictive eschar that can compromise the airway. Make paired vertical incisions on the posterolateral surfaces of the neck from the mastoid process to the clavicle (Figure 139-3A). **Meticulous care and attention should be given to always remain posterior to the clavicular border of the sternocleidomastoid muscle.** This will avoid injury to the internal jugular vein, carotid artery, thyroid gland, trachea, and vagus nerve.

TORSO ESCHAROTOMY

Perform a thoracic escharotomy by extending bilateral vertical incisions from the lateral clavicle to the costal margins along the anterior axillary lines (Figures 139-2B and 139-3B). Use caution in female patients to avoid incising directly through the breast tissue. Instruct an assistant to grasp the breast and move it medially to avoid the escharotomy incision line. Extend the thoracic incision inferiorly beyond the costal margins and across the entire eschar to ensure adequate decompression in patients whose burns involve a significant portion of the abdominal wall (Figures 139-2B and 139-3B). Make a horizontal bridging incision along the inferior costal margin in patients whose burns extend from the thorax and onto the abdomen to support proper respiratory mechanics (Figure 139-2B).

Circumferential burns of the penis require an escharotomy to decompress the area and prevent ischemia. Distal ischemia can rapidly progress and produce significant tissue loss. Make bilateral incisions along the lateral margins of the body of the penis. **Meticulous care and attention should be given to avoid injuring the dorsally located neurovascular structures that lie between the 10 o'clock and the 2 o'clock position.**

UPPER EXTREMITY ESCHAROTOMY

Perform an upper extremity escharotomy on the medial and lateral aspects of the involved limb, extended along the line dividing the flexor and extensor surfaces (**Figure 139-3B**). Place the upper extremity supine to ensure adequate landmark identification. The areas surrounding joints are sites of severe potential restriction due to relatively tight tissue adherence. Use caution when extending the incisions across these locations. **Meticulous care and attention should be given to avoid the ulnar nerve along the medial surface of the elbow as it courses posterior to the median epicondyle and the superficial branch of the radial nerve along the lateral surface of the wrist as it courses superficially above the radius.**

Extend the forearm incisions to include the thenar and hypothenar eminences if the hand is involved (**Figure 139-3C**). Further hand decompression can be accomplished by making vertical incisions down the four intermetacarpal grooves on the dorsum of the hand (**Figures 139-3C and 139-4**). The fingers can be decompressed with linear incisions along the middle of the radial and ulnar surfaces, between the flexor and extensor surfaces (**Figures 139-3C and 139-4**). **Limit the potential damage to a patient's grasping surfaces.** Incise the ulnar finger surfaces or the radial surface on the thumb. Assess whether this unilateral incision is adequate to restore perfusion prior to automatically incising the corresponding opposing surface.¹⁸

LOWER EXTREMITY ESCHAROTOMY

The lower extremity should be approached with the incisions extending along the groove between the flexor and extensor surfaces (**Figure 139-3B**). **Meticulous care and attention should be given to avoid damaging the common peroneal nerve along the lateral knee as it courses superficial to the fibular head and the posterior tibial artery along the medial ankle as it courses posterior to the medial malleolus.** Extend the incisions along the medial and lateral borders of the foot to the great toe and the fifth toe, respectively, if the foot is involved (**Figure 139-3B**). Decompress the toes in a manner like the fingers.

TECHNIQUE FOR PEDIATRIC PATIENTS

Pediatric patients have a higher surface area-to-volume ratio than do adults. Burns pose a greater risk for significant external fluid losses and the rate of fluid resuscitation needs to be

FIGURE 139-4. Escharotomies of the hand and fingers. (Used with permission from reference 15.)

adjusted. More aggressive fluid resuscitation increases the likelihood for pathologically significant elevations in the perfusion pressures of affected tissues. **Infants and younger children depend on diaphragmatic excursion and abdominal wall mobility for normal respiratory function.** They are more susceptible to significant respiratory compromise from extensive truncal burns. This necessitates that the treating Emergency Physician possesses a high index of suspicion and the technical ability to intervene surgically. The patient preparation and escharotomy techniques are the same as in an adult.

ASSESSMENT

The response to an escharotomy should be almost immediate with the signs of improving distal perfusion of the extremities or improved ventilation. The distal extremity should demonstrate decreased pallor and return of a natural skin color, return of sensation, appropriate Doppler arterial flow, and appropriate pulse oximetry. Distal pulse oximetry readings should rapidly climb into a normal range provided adequate respiratory mechanics.¹⁹ **Lack of improvement in distal perfusion should alert the Emergency Physician to either an inadequate surgical decompression or an insufficient fluid resuscitation.** No improvement in perfusion despite appropriately addressing these two concerns requires consideration of an underlying compartment syndrome that would require an emergent fasciotomy (Chapters 93 and 94).

AFTERCARE

Continued routine burn care and fluid resuscitation as necessary. Manage any continued bleeding from the escharotomy incisions with the application of pressure or electrocautery. Cover the escharotomy incisions with sterile saline-soaked gauze and an outer dressing. Frequently reassess the patient to rule out the development of additional tissue ischemia or respiratory compromise that would indicate the need for further extension of the initial escharotomy incisions. Transfer the patient to a specialized burn center or an intensive care unit to continuously monitor and manage the patient.

COMPLICATIONS

Bleeding can be a significant complication. This is rare when the escharotomy incisions are properly limited to the dermis. Bleeding can be extensive when an underlying subcutaneous vessel is incised. This is often complicated by the consumptive coagulopathy that frequently accompanies these burns. Electrocautery is an attractive option to limit such bleeding. Direct pressure should otherwise generally suffice. Some blood vessels may require ligation for definitive hemostasis.

The burn-damaged epidermis can no longer function to protect deeper tissues from the external environment. The overlying eschar of necrotic tissue provides an ideal environment for uncontrolled bacterial colonization. Escharotomy incisions provide a direct route for bacterial penetration into susceptible subcutaneous tissues if sterile precautions are not properly maintained. This can result in catastrophic infection and burn sepsis.

Inadvertent injury of deeper structures (e.g., blood vessels, nerves, and tendons) can occur. This is preventable by controlling the depth of the incisions and not extending into and through the subcutaneous tissues. This is especially true when incising over high-risk areas.

Making an escharotomy incision on the fingers is controversial. There is little to no muscle at risk of ischemia in the fingers. The fingers primarily consist of bone, ligaments, subcutaneous fat, and tendons. These structures are quite resistant to ischemia. A finger

escharotomy can expose the metacarpophalangeal and interphalangeal joints, make them prone to infection, and require a subsequent fusion or amputation.

A final complication is the inadequate release of the overlying restrictive eschar. Ongoing tissue ischemia can lead to permanent disability from disfiguring muscle contractures, irreparable neurologic damage, or limb loss. Rhabdomyolysis can lead to life-threatening electrolyte abnormalities and acute renal failure. Several authors advocate extending the escharotomy incisions 1 to 2 cm beyond the eschar border into viable tissue. A secondary reperfusion injury can follow the primary decompression as blood once again streams into previously hypoperfused tissue. The consequent swelling can cause the formation of a secondary underlying intrafascial compartment syndrome.

SUMMARY

Thermal burns are frequently encountered injuries prompting patients to seek medical care. Their associated morbidity, mortality, and costs of treatment can be astronomical. Emergency Physicians often provide an essential role in the acute resuscitation and stabilization of these patients prior to their ideal transfer to a specialized burn center. Severe burns can destroy the natural elastic properties of skin and result in the formation of constrictive overlying eschars. These eschars can result in catastrophic limb loss, airway compromise, or respiratory failure. An escharotomy can be a limb-saving and life-saving procedure that grants the patient a significant chance to undergo more specialized and definitive burn care.

Subcutaneous Hydration (Hypodermoclysis)

Mary J. O

INTRODUCTION

Subcutaneous rehydration therapy (SCRT), also known as hypodermoclysis, is a method of fluid replacement first described in the 1880s as a proposed treatment for cholera in India.¹ It involves the infusion of fluids into the subcutaneous space where it slowly diffuses into the circulation.² This method was widely used for rehydration until the 1950s until it was superseded by the intravenous (IV) route.³ This was due to reports of serious adverse events that were most likely caused by improper choice of fluids for SCRT (e.g., shock secondary to osmotic shift caused by infusion of hypertonic or electrolyte-free fluids).⁴ Subsequent studies have confirmed the safety and efficacy of hypodermoclysis.

SCRT offers many advantages over IV hydration. It is often much easier to obtain and maintain access in patients who may be dehydrated with collapsible veins, agitated, at risk of pulling out IV lines. Nursing time to obtain subcutaneous access is less than with IV access.⁵ SCRT does not cause thrombophlebitis and there is less risk of fluid overload than with IV fluid administration.⁶ The popularity of SCRT is once again increasing in geriatrics, palliative care, and limited-resource environments. Its use remains unfamiliar to and overlooked by many Emergency Physicians.

ANATOMY AND PATHOPHYSIOLOGY

Hyaluronidases are enzymes that break down hyaluronic acid, a compound found in the intercellular matrix responsible for stabilizing the structure of the connective tissue.¹ They are commonly used for subcutaneous hydration, extravasation of hyperosmolar radiologic contrast, and eye surgery.

Hyaluronidases are divided into three groups or classes (**Figure 140-1**).⁷ These include the β -endoglucuronidases (found in hookworms and leeches), endo- β -N-acetyl-D-hexosaminidases (found in ants, bees, hornets, mammalian testicles, wasps, and yellow jackets), and the hyaluronic acid lyases (found in bacteria). They all are responsible for the hydrolysis of bonds in hyaluronic acid. These enzymes are responsible for insect venom spreading and causing allergic reactions. There are numerous forms that are available for human use (**Table 140-1**). Hyaluronidase is inactivated by blood.

Hyaluronidase temporarily breaks down the extracellular matrix and allows infused fluid to be absorbed up to five times more rapidly, decreasing the amount of localized edema, and increasing efficiency of SCRT.⁸ The matrix will rebuild itself within 24 to 48 hours after the injection of hyaluronidase. Its use in hypodermoclysis is optional but helpful.⁹⁻¹¹

Preferred injection sites are the upper back in between scapulae, anterolateral thighs, anterior abdomen sparing a 2.5 cm diameter

FIGURE 140-1. The action of various classes of hyaluronidases. (Used from reference 7.)

around the navel, and the subclavicular chest wall sparing breast tissue (Figure 140-2). The outer sides of the upper arms may be used if other sites are unavailable. Subcutaneous tissue tends to diminish in peripheral areas with age and more centrally located sites are preferred for infusion.¹²

The advantages of hypodermoclysis are numerous. The insertion of the catheter is easier than an IV catheter and less painful. It has fewer complications than IV access. It avoids the first-pass elimination by flowing through the liver. It needs less nursing supervision, needs less equipment, and costs are lower than with IV access. The IV is avoided in those with a needle phobia. Hypodermoclysis can be used for several days. It does not cause thrombophlebitis, venous clotting, or IV catheter clotting, and has few local effects. It does not cause fluid overload because of the limited fluid administered. Patients are unlikely to experience systemic symptoms from fluid administration.

There are numerous disadvantages to hypodermoclysis. The volume administered is limited. Hypodermoclysis causes local edema that resolves after the infusion is stopped. Only administer isotonic fluids. A limited amount of medications can be given subcutaneously (Table 140-2). Fluid is limited to that which is isotonic. Fluid is given by a drip to gravity and not a pump. Different rates of absorption occur in different people. Fluid boluses and rapid administration cannot be given. Each site is limited to 1500 mL in 24 hours, with two sites simultaneously used. It rarely happens that two sites are used simultaneously. Hypodermoclysis does not work well if edema is present. Hypodermoclysis can result in hemorrhage in patients who are anticoagulated or have bleeding disorders. Emergency Physicians lack the information and experience with this technique.

INDICATIONS

Hypodermoclysis may benefit patients who are mildly to moderately dehydrated, in whom IV access is difficult or impractical, and oral hydration is not possible.¹³⁻¹⁹ It may also serve as a bridge to IV therapy in stable patients whose veins are initially collapsed due to dehydration. It may result in an increased chance of successful venous cannulation after receiving SCRT. Hypodermoclysis is often used for hydration in end-of-life care in the hospice patient. It can

be used to administer medications for nausea and vomiting, seizures, pain management, and gamma-globulin (Table 140-2).

CONTRAINDICATIONS

SCRT is contraindicated in emergent or life-threatening situations when large and rapid fluid boluses are needed. It should not be used in patients who will require more than 3 L of fluid replacement in a 24-hour period. It is contraindicated in patients with significant peripheral edema as this interferes with the absorption of fluids deposited into the subcutaneous space. Hypodermoclysis should also be avoided in severely cachectic patients who have minimal subcutaneous tissue. Avoid skin sites that are broken, inflamed, infected, burned, scarred, or irradiated. Do not use sites near joints, bones, skin folds, tumors, or large blood vessels. The patient or their caregiver may refuse hypodermoclysis. Avoid infected or inflamed areas as hypodermoclysis can spread a localized infection. Avoid hypodermoclysis in the patient with anticoagulation, blood dyscrasias, circulatory failure, fluid overload states (e.g., congestive heart failure and renal failure), poor skin integrity, severe dehydration, severe electrolyte abnormalities, and shock. Do not use fluids that are hypertonic or hypotonic. Many medications are either not compatible for subcutaneous administration or are not tested.

Allergic reactions, anaphylaxis, and hypersensitivity to hyaluronidase can occur with animal-derived hyaluronidase. This is less likely

FIGURE 140-2. The potential sites for hypodermoclysis. (Used with permission from reference 23.)

TABLE 140-2 Medications and Their Relation to Subcutaneous Use

Can be used		
Ampicillin	Fentanyl	Metoclopramide
Atropine	Furosemide	Midazolam
Cefepime	Glycopyrrolate	Morphine
Cefotaxime	Granisetron	Naproxen
Ceftazidime	Haloperidol	Octreotide
Ceftriaxone	Hydromorphone	Ondansetron
Chlorpromazine	Hydroxyzine	Phenobarbital
Clonazepam	Ketamine	Potassium
Cyclizine	Ketorolac	Promethazine
Dexamethasone	Levomopromazine	Ranitidine
Diclofenac	Local anesthetics	Scopolamine
Dipyron	Lorazepam	Tobramycin
Diphenhydramine	Methadone	Tramadol
Famotidine		
Cannot be used		
Alpha-agonists	Diazepam	Phenytoin
Compazine	Dopamine	Thorazine

for the recombinant hyaluronidase. A skin test can be used to check for sensitivity. Inject 0.02 mL (3 units) intradermally of a 150 U/mL solution. A positive reaction is a skin wheal within 5 minutes that persists for 20 to 30 minutes.

EQUIPMENT

- Alcohol swab
- Chlorhexidine or povidone iodine
- 21 or 23 gauge butterfly needle or angiocatheter
- Commercial subcutaneous infusion device, optional
- Parenteral fluid
- Tubing with drip chamber, primed with the chosen solution
- Transparent dressing
- Tape
- Hyaluronidase (Table 140-1)

There are commercially available subcutaneous infusion devices that may be used in place of the standard butterfly needle or angiocatheter (Figures 140-3 and 140-4). They include the Saf-T-Intima (Becton Dickinson, Franklin Lakes, NJ), the Aqua-C (Norfolk Medical, Skokie, IL), and the ClearView Sub-Q (Norfolk Medical, Skokie, IL). These devices are discussed below. Other devices less used in the Emergency Department are made by MarCal Medical (Millersville, MD) and Churchill Medical Systems (Lansdale, PA). The advantages of these devices are the increased ease of use and the use of catheters that are designed to remain in place longer. These devices are costlier than using an angiocatheter or butterfly needle.

Electrolyte-free fluids (e.g., dextrose 5% in water) have been reported to draw fluid into the interstitial space causing third-spacing and cardiovascular collapse.⁴ These solutions should be avoided.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Assemble all necessary equipment. Wash hands thoroughly or use an alcohol-based hand cleaner. Don a clean pair of gloves. Prime the infusion tubing with the chosen fluid. Select an appropriate site for subcutaneous hydration. Clean and prepare the skin site. Clean any dirt and debris from the skin. Apply chlorhexidine or povidone iodine to the skin and allow it to dry. Cleaning off the chlorhexidine or povidone iodine with an alcohol swab is optional.

TECHNIQUES

SAF-T-INTIMA

The Saf-T-Intima was designed for hypodermoclysis (Becton Dickinson, Franklin Lakes, NJ). It is a butterfly-type catheter (Figure 140-3C). Grasp the catheter (Figure 140-5A). Grasp the clean and prepared skin with a thumb and index finger (Figure 140-5B). Grasp an area of approximately 2.5 cm

FIGURE 140-3. The catheters used for hypodermoclysis. A. The butterfly. B. The angiocatheter. C. The Becton Dickinson Saf-T-Intima.

FIGURE 140-4. Some of the devices used for hypodermoclysis. **A.** The ClearView Sub-Q. **B.** The Aqua-C.

surrounding the insertion site to separate the subcutaneous space from the underlying muscle (**Figure 140-5B**). Lift the skin upward. Insert the needle with the bevel up and at a 30° to 45° angle into the subcutaneous space located at the base of the area pinched. Advance the needle until the catheter hub is against the skin. Immediately withdraw the needle and select a new insertion site at least 2.5 cm away if blood appears in the tubing. Hold the catheter hub and remove the needle. Lay the catheter and tubing flat against the skin and hold the wings of the butterfly (**Figure 140-5C**).

If using hyaluronidase, inject the desired amount through the catheter.¹¹ This is usually 1 mL of 150 U/mL. Attach the primed IV tubing to the catheter. Secure the catheter with tape and a transparent dressing (**Figure 140-5D**). Start the IV fluid flowing.

The recommended infusion rate is 1 to 2 mL/min or approximately 1.5 to 3 L/day with a maximum of 1.5 L at each site.² Small studies have reported patients tolerating boluses of up to 500 mL/hr with the use of hyaluronidase. This requires the use of up to 750 units of hyaluronidase.¹⁰

ANGIOCATHETER

Use an angiocatheter or butterfly needle if a Saf-T-Intima is unavailable. Grasp the angiocatheter. Grasp the clean and prepared skin with a thumb and index finger. Grasp an area of approximately

FIGURE 140-5. Hypodermoclysis using the Saf-T-Intima catheter. **A.** Holding the device. **B.** Inserting the device. **C.** Stabilization of the device. **D.** Securing the device.

2.5 cm surrounding the insertion site to separate the subcutaneous space from the underlying muscle. Lift the skin upward. Insert the needle with the bevel up and at a 30° to 45° angle into the subcutaneous space located at the base of the area pinched. Advance the angiocatheter until the catheter hub is against the skin. Immediately withdraw the needle and select a new insertion site at least 2.5 cm away if blood appears in the tubing. Hold the catheter hub and remove the needle. Lay the catheter and tubing flat against the skin.

If using hyaluronidase, inject the desired amount through the catheter.¹¹ This is usually 1 mL of 150 U/mL. Attach the primed IV tubing to the catheter. Secure the catheter with tape and a transparent dressing. Start the IV fluid flowing.

The recommended infusion rate is 1 to 2 mL/min or approximately 1.5 to 3 L/day with a maximum of 1.5 L at each site.² Small studies have reported patients tolerating boluses of up to 500 mL/hr with the use of hyaluronidase. This requires the use of up to 750 units of hyaluronidase.¹⁰

COMMERCIAL DEVICES

The insertion of a commercial device is simple. Clean and prepare the skin as described previously. Insert the Aqua-C or ClearView Sub-Q perpendicular to the skin. Push the unit until it is flat against the patient's skin. The needle only penetrates a certain depth and into the subcutaneous tissue. Inject hyaluronidase, attach IV tubing, start the fluid infusion, and secure the catheter as described above.

PEDIATRIC CONSIDERATIONS

The use of hypodermoclysis in pediatric patients is similar to that in adults. There have been a few studies showing that SCRT may be a reasonable alternative to IV therapy in children but it is not yet included in current guidelines for the management of dehydration.^{8,20,21} Only inject 1 mL of the 150 U/mL hyaluronidase and begin the infusion. Continued research will be needed to clarify the safety and role of SCRT in the pediatric population.

AFTERCARE

Initial swelling is expected at the insertion site when fluids start infusing. This will resolve after completion of the infusion. Check the infusion site for signs of redness, tenderness, or leakage at least once every 4 hours. Switch the site if any of the above are seen, if the patient has discomfort, or the patient has significant swelling. Raise the IV fluids if the drip is running slow. Switch the site if it continues to flow slowly. Observe the painful site for any signs of infection. Change the site if blood backflows at any time into the tubing. Pooling of fluid at the site can reduce the flow rate. Change the site. Bruising results from a blood vessel leaking. Change the site.

COMPLICATIONS

SCRT generally has fewer complications compared to IV hydration and most complications are not significant. The most common complications are local reactions (e.g., inflammation, swelling, redness), extravasation, bleeding, and bruising.^{1,22} Swelling is mostly attributed to the rapid rate of infusion and can be lessened by local massage, slowing the flow rate, or diuretics. Do not use hypotonic or hypertonic solutions. Accidental venipuncture can occur. There have been rare reports of pulmonary edema due to fluid overload, although this rate is much lower than with IV fluid administration.⁵ The use of hyaluronidase may produce a local allergic reaction, although the switch to a human recombinant version from an animal-derived version has lessened this risk. Rotate the site if complications are noted, if a dose of over 2000 mL is administered, if used over 24 hours, or as needed for patient positioning.

SUMMARY

Subcutaneous hydration or hypodermoclysis is an alternative method for rehydration that offers many advantages over the IV route. It is a safe, simple, and effective method of fluid administration to help correct mild to moderate dehydration with few side effects. The rate of fluid absorption is much slower than with IV access. Hypodermoclysis should not be used as a substitute for the IV route in life-threatening situations when large and rapid fluid boluses are required. The role of SCRT in the pediatric population continues to be investigated.

Subcutaneous Extravasation and Infiltration Management

Henry Swoboda

INTRODUCTION

Extravasation and infiltration events are common occurrences with intravenous (IV) therapy and diagnostics (Figure 141-1). Some sources cite an incidence of 10% to 30%.¹ The incidence of extravasation of specific agents (e.g., intravenous contrast or vasopressors) is low.^{2,3} Carefully placed IV catheters for chemotherapy have an incidence of extravasation as low as 0.01%.⁴ Acute chemotherapeutic medication extravasations are infrequently encountered in the Emergency Department. **Understanding extravasations and their treatment is important due to the high degree of morbidity, the limited application of antidotes, and the increasing presence of standalone Emergency Departments and infusion centers.**⁵ An understanding of the early recognition and treatment of chemotherapeutic extravasations is increasingly important.⁶

Most extravasations cause some degree of discomfort for the patient but display limited associated toxicity.^{3,7,8} There is swelling distal or proximal to the IV site with the extravasate. The dependent portion of the limb swells. There is skin tightness at the IV site. This can be increased over an area depending on the amount of extravasation. The skin can be blanched and cool to the touch. Extravasation can stop the infusion and set off alarms on the IV pump. Extravasation may seep onto the skin and wet dressings. The Infusion Nurses Society has developed an infiltration and extravasation scale (Table 141-1).⁹

FIGURE 141-1. Subcutaneous infiltration of radiologic contrast. (Courtesy of Eric Heffernan, MD, and www.svoehradiology.ie.)

TABLE 141-1 The Infusion Nurses Society Infiltration and Extravasation Scale

Grade	Criteria
0	No symptoms
1	Cool skin to the touch Edema in any direction of < 2.5 cm Pain may or may not be present Skin blanched
2	Cool skin to the touch Edema in any direction of 2.5–15.0 cm Pain may or may not be present Skin blanched
3	Cool skin to the touch Edema in any direction of > 15.0 cm Numbness may or may not be present Pain is mild to moderate Skin blanched or translucent
4	Circulation impairment Cool skin to the touch Edema in any direction of > 15.0 cm Infiltration of blood products, irritants, or vesicants Pain is moderate to severe Pitting edema Skin blanched or translucent Skin bruised, discolored, swollen Skin tight and leaking

Prevention of extravasation of medications with known toxicity is a key focus to prevent morbidity. Anything administered in an IV may infiltrate and extravasate into the extremity. Certain medications cause tissue damage when extravasated (Table 141-2). **It is recommended that medications with known extravasation toxicity be administered via a central venous catheter in non-emergent situations.**¹⁰ This can limit but does not eliminate extravasation.¹⁰ Sometimes central venous access is impractical for the administration of potentially toxic medications.¹¹ **Morbidity from extravasation may be minimized by frequent checks of the IV site during potentially toxic drug administration and using recently placed forearm IVs with progression from distal to proximal in placement attempts.** Extravasations in the antecubital fossa carry a high degree of morbidity.¹² Extravasation frequency increases in IVs placed near joints.¹²

Some agents have specific “antidotes” or therapies that are recommended in the event of extravasation (Table 141-3). There is poor-quality evidence supporting their use. The recommendations are based on known risks and theoretical benefits.^{3,13} Warm compresses are recommended for agents in which increased blood flow and dispersal of the offending agent is desired. Cold compresses are ideal when limitation of inflammation and cytotoxicity is desired. The use of topical, intralesional, or systemic corticosteroids has been advocated. They are not recommended due to conflicting and negative data, lack of an inflammatory cause of tissue damage in most cases, and known deleterious effects on wound healing.^{7,14} The use of a washout technique has mixed recommendations.¹³ Routine surgical or washout procedures are not recommended due the poor supporting evidence and potential morbidity related to the procedures. Consider a saline washout with or without hyaluronidase in severe extravasations (e.g., those with extreme pain; significant swelling due to large-volume extravasation; clear erythema, blistering, or vascular compromise to the overlying tissue; or involving known vesicant medications without an available antidote).^{6,15,16}

Many other specific therapies have been proposed. There are scant data to support their use and evidence of possible harm. Use

TABLE 141-2 Fluids and Medications That Can Cause Tissue Damage after Extravasation

Fluids	
Blood products	Furosemide
Calcium-containing fluids	Haldol
Dextrose solutions $\geq 10\%$	Interferon
Electrolytes	Interleukin
Hyperosmolar solutions	Ketamine
Hypertonic glucose	Mitomycin
Hypertonic saline	Mitoxantrone
Mannitol $\geq 20\%$	Nafcillin
Potassium-containing fluids	Norepinephrine
Potential for any fluid ≥ 60 mEq/L	Quinine
Sodium bicarbonate	Paclitaxel
Sodium chloride $\geq 30\%$	Pancuronium
Total parenteral nutrition	Penicillins
Medications

Buprenorphine	Remifentanyl
Chemotherapy agents	Sedatives
Chlordiazepoxide	Tetracyclines
Contrast media	Thiamine
Dactinomycin	Thiopental
Daunorubicin	Valproate
Diazepam	Vancomycin
Digoxin	Vasopressin
Dobutamine	Vasopressors
Dopamine	Verapamil
Doxorubicin	Vinblastine
Epinephrine	Vincristine
Fentanyl	Vindesine
	Vinorelbine

alternative therapies based on expert preference and institutional protocol. Therapies recommended in this chapter have a relatively low risk-to-benefit ratio for the management of severe extravasations. It is best to initiate a specific therapy without delay as many of the effects are considered time-dependent. Obtain a surgical consultation based on institutional policy, need for follow-up, and severity of the extravasation. Onset of toxicity for vesicant medications may be delayed.⁶ These patients may benefit from surgical consultation and a washout up to 72 hours after the extravasation.¹⁶

Extravasation injuries typically occur after IV catheter displacement with ensuing localized swelling, burning, pain, and blanching or erythema. Recognition can be delayed in patients with abnormal mental status. Skin ulcerations and damage are frequent and not initially apparent. Injuries can progress to full-thickness skin sloughing in a delayed fashion. Subcutaneous extravasations can be managed via the general approach outlined in this chapter, in conjunction with the treatments listed in **Table 141-3**, and described in their respective sections.

Extravasations from chest and neck central venous access devices carry extremely high morbidity. These injuries typically present with chest pain and benefit from emergent aspiration of the extravasate, consideration of computed tomography scanning, and emergent surgical consultation.⁷ Further discussion of extravasation from central venous catheters is outside of the scope of this chapter.

TABLE 141-3 Treatment of Common Extravasations

Nonchemotherapeutic medications	Treatment(s)
Concentrated electrolyte solutions (e.g., NaHCO ₃ , KCL, CaCl, NaCl, MgSO ₄)	Warm compresses Consider hyaluronidase
Hypertonic solutions (e.g., D25, D50, total parenteral nutrition, radiographic contrast)	
Hyperosmolar, caustic, or vesicant medications (e.g., arginine, aminophylline, chloramphenicol, mannitol, ampicillin, oxacillin, nafcillin, propofol)	
Vasopressors	Warm compresses plus phentolamine or Terbutaline or 2% Nitroglycerin ointment
Phenytoin	Warm compresses
Promethazine	Frequent neurovascular checks Consider vascular imaging Consider Surgeon consultation
Chemotherapeutic medications	Treatment(s)
Etoposide	Warm compresses
Taxanes (paclitaxel, docetaxel)	Hyaluronidase
Vinca alkaloids (vinblastine, vincristine)	
Anthracyclines (doxorubicin, daunorubicin, epirubicin)	Cold compresses Dextrazoxane or DMSO
Bendamustine	Cold compresses
Cisplatin	Sodium thiosulfate
Mechlorethamine	
Mitomycin	Cold compresses DMSO

ANATOMY AND PATHOPHYSIOLOGY

Most extravasation toxicity is caused by one of four mechanisms. Tissue damage can be caused by (1) vasospasm and perfusion abnormalities related to vasoactive medications, (2) cellular dehydration and direct toxic effects of hyperosmolar medications, (3) pH-related tissue damage, or (4) direct cytotoxicity from vesicant chemotherapeutic medications.^{2,3,17} Chemotherapeutics can be divided into vesicants and irritants with some overlap. Vesicant chemotherapeutics are typically associated with severe tissue damage while irritant chemotherapeutics are not. These compounds can be further classified as DNA-binding versus non-DNA-binding. The latter's concentration-dependent toxicity is more amenable to drug dispersion techniques.⁷ Mechanical complications can occur from large-volume extravasation from IV or intraosseous catheters. These can cause direct compression of soft tissues or a compartment syndrome (Chapters 93 and 94). Treatment of a compartment syndrome is based on clinical evaluation, compartment pressures, and surgical consultation. Management of volume-related complications should focus on prevention and surveillance.^{18,19} Dispersion of the extravasate is the aim of many treatments.^{18,19} Examples of extravasated medications associated with tissue toxicity and their accompanying suggested treatments are listed in **Table 141-3**.

VASOPRESSOR EXTRAVASATION

There is support for the limited administration of vasopressors through peripheral IV catheters.¹¹ Administer ongoing vasopressors through a central venous catheter due to the potential morbidity associated with extravasations.²⁰ The management of vasopressor extravasation can include antidotes (e.g., nitroglycerine paste, phentolamine, or terbutaline) (**Figure 141-2**). Phentolamine is considered first-line therapy and is approved by the U.S. Food and Drug Administration (FDA) for norepinephrine extravasations. Its

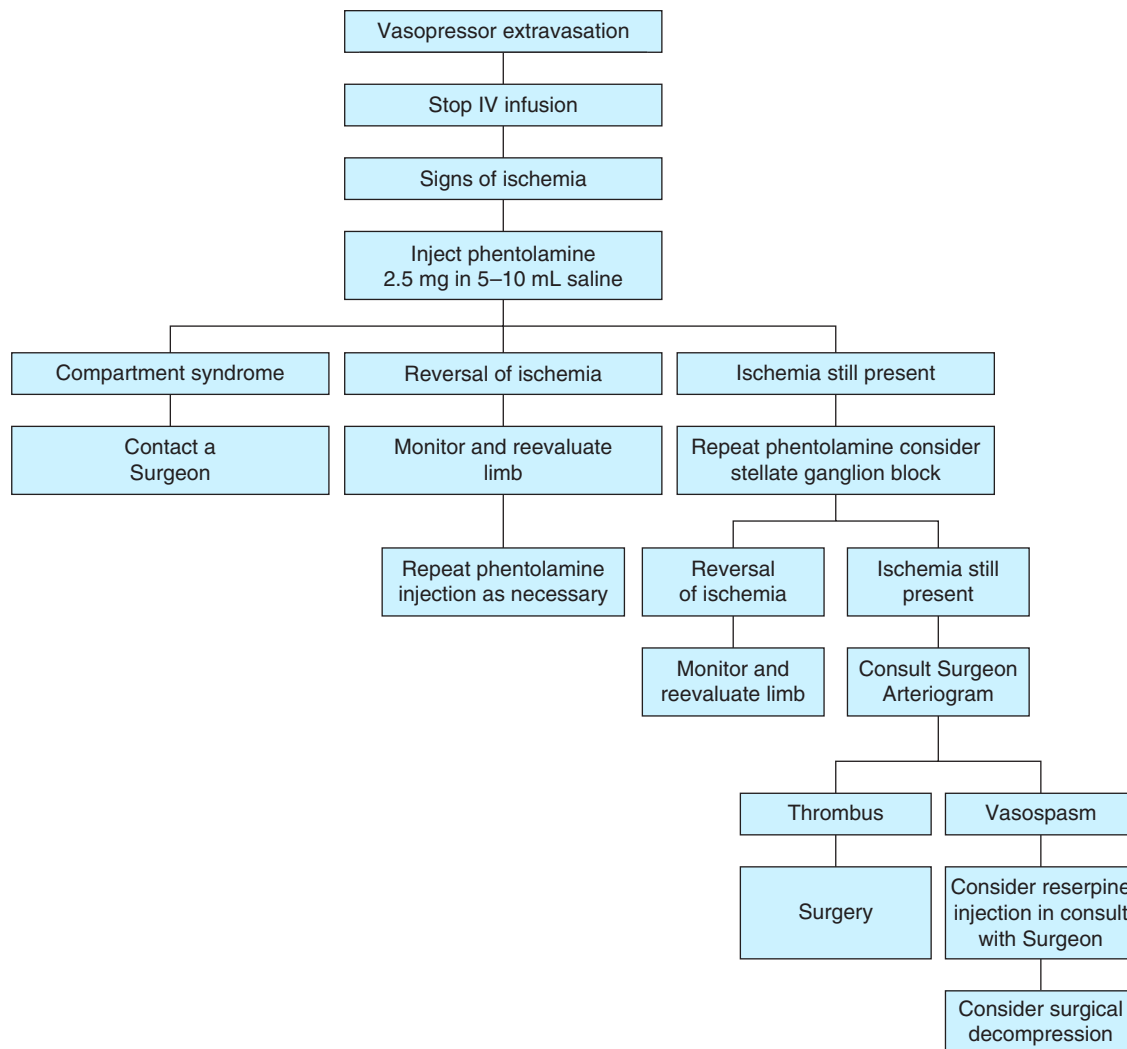

FIGURE 141-2. Treatment of vasopressor extravasation.

alpha-adrenergic antagonism is a focused therapy for all vasopressors with alpha-adrenergic agonism.³ Phentolamine can be used as a nonspecific therapy for other vasopressor extravasations.³

NONNEOPLASTIC MEDICATION EXTRAVASATION

Medications and electrolyte solutions that have an osmolarity greater than 600 mOsm/L have the potential to cause tissue damage via cellular dehydration and osmotic stress (**Table 141-2**).³ Calcium salts have been associated with significant morbidity due to protein precipitation and vasospasm. Hyaluronidase is a medication that increases connective tissue permeability via the temporary hydrolysis of hyaluronic acid. There is a significant amount of low-quality evidence supporting the safe use of hyaluronidase as a dispersion agent in extravasations. Administration of hyaluronidase can be combined with a washout procedure or it can be used independently. A new, ready-to-use recombinant product has replaced the old powdered formulation. The dosing recommendations have changed.

Local toxicity may occur from medications containing propylene glycol as a preservative (e.g., diazepam, digoxin, etomidate, lorazepam, nitroglycerin, phenobarbital, and phenytoin). Some medication solutions have pHs within the caustic range (e.g., acyclovir, amiodarone, conivaptan, doxycycline, pentamidine, phenytoin, promethazine, thiopental, and vancomycin). Treatment for these extravasations includes warm compresses and routine wound care. Hyaluronidase has been suggested for refractory cases. **Do not attempt neutralization.**³

Phenytoin administration has been associated with vascular occlusion and local toxicity, referred to as the purple glove syndrome (PGS).²¹ No extravasation is detected in most cases. The PGS may be due to micro-extravasation and other mechanisms. Patients with suspicion for PGS require close neurovascular monitoring, aggressive vascular imaging, and early Surgeon consultation. PGS is rare, consistently reported, and all specific treatments (e.g., heparin and hyaluronidase) are unproven. PGS has been associated with extravasation, intraarterial administration, undiluted medication administration, use of small IV catheters, distal IV location, and concomitant administration of other vesicants.²² Over 95% of reported cases were associated with one of these factors.²² Their routine avoidance in phenytoin administration would be prudent.²² Use of fosphenytoin may decrease the incidence of PGS.

Promethazine has been associated with a similar syndrome in the setting of extravasation or intraarterial injection. There are similarly no proven therapies even though some advocate for sympathetic block and heparinization. The focus has been on prevention by using a dilute solution and employing intramuscular or slow IV administration.³

CONTRAST EXTRAVASATION

Extravasation of IV contrast is an infrequent event (**Figures 141-1 and 141-3**). Studies indicate an incidence of 0.34% to 0.7% of contrast administrations. It remains an important issue given the common use of IV contrast for imaging (e.g., > 10,000 administrations

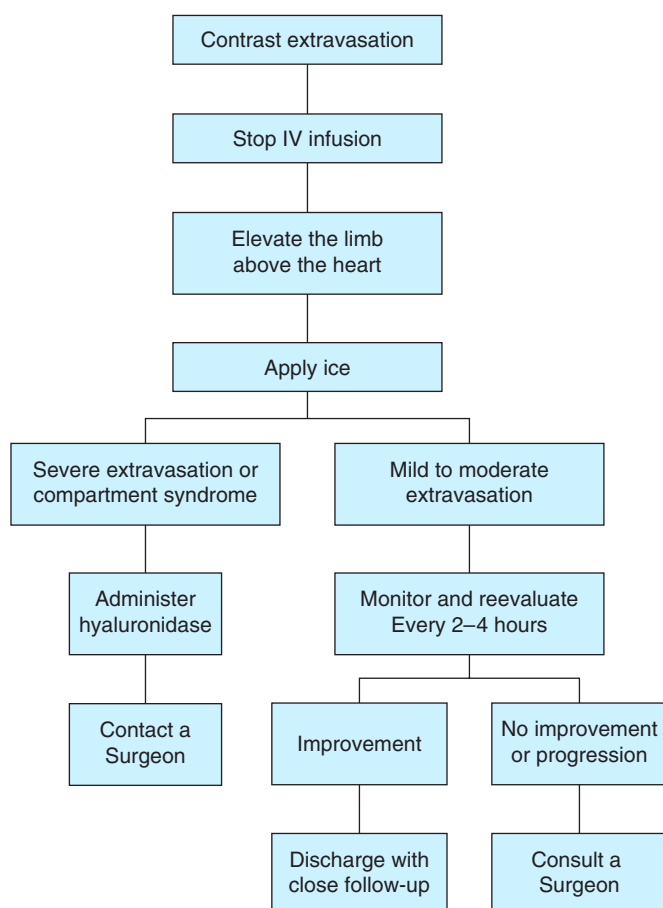

FIGURE 141-3. Treatment of contrast extravasation.

per year at high-volume institutions).^{23,24} Severe injuries from contrast extravasations have decreased greatly with the advent of low osmolarity IV contrast. **Most contrast extravasations have minimal associated toxicity. Patients do well with observation and conservative management.** High-risk features include extremes of age, preexisting subcutaneous atrophy, distal IV placement, compromised vascular or lymphatic flow, use of a power injector, high osmolar contrast extravasation, and high-volume (> 50 mL) extravasation.

CHEMOTHERAPEUTIC EXTRAVASATION

Chemotherapeutics are divided into vesicants and irritants based on their potential tissue toxicity. The vesicants are associated with potentially severe toxicity and skin sloughing. Both classes of medications have been associated with local skin reactions during infusion. This can confound the early diagnosis of extravasation. Local reactions frequently resolve quickly once the infusion is stopped. Treat reactions observed by experienced personnel concerning for extravasation. Chemotherapeutic agents have a wide range of toxicities depending upon their mechanism of action. Antidotes are most frequently employed for vesicant chemotherapeutics due to the severity of their toxicity.

Special attention has been paid to increasing dispersion for extravasations of vinca alkaloids (e.g., vincristine and vinblastine) and epipodophyllotoxins (e.g., etoposide) with hyaluronidase and the use of warm compresses. Cold compresses may cause harm.

Dimethylsulfoxide (DMSO) is a free radical scavenger that has been used for a variety of extravasation injuries. It is currently indicated for extravasations of dactinomycin and mitomycin. Apply 99% DMSO (or the highest concentration as available) topically at

the site of extravasation. This can be accomplished in the outpatient setting.²⁵

Extravasation of nonliposomal anthracyclines (e.g., doxorubicin, daunorubicin, and epirubicin) has been associated with full-thickness skin sloughing and severe toxicity in up to 50% of cases.²⁶ These cases are subject to aggressive treatment. Dexrazoxane is an iron chelator and antidote used for systemic anthracycline toxicity. It is FDA approved for use in local extravasation injury.

The extravasation of mechlorethamine or a high-risk extravasation of cisplatin or bendamustine (e.g., overlying a joint, a high concentration, or a large volume) can be deactivated with 4% sodium thiosulfate. Manage other chemotherapy extravasations with cold packs and general management as described below.²⁷

INDICATIONS

Phentolamine is indicated for significant vasopressor extravasation. Terbutaline and/or nitroglycerin ointment can be administered for vasopressor extravasation if phentolamine is not available. Hyaluronidase is specifically indicated for vinca alkaloid extravasation, potentially for high osmolar substances, and large radiographic contrast extravasations. Sodium thiosulfate is indicated for mechlorethamine, bendamustine, and cisplatin extravasations. Administer DMSO for mitomycin extravasations and for anthracycline extravasations if dexrazoxane is not available. Administer dexrazoxane for confirmed anthracycline extravasations that occurred within 6 hours. Use the saline washout technique for severe extravasations of medications without an available antidote or as directed by a surgical consultant.

CONTRAINDICATIONS

Do not give DMSO with dexrazoxane. Do not use the saline washout technique with mild extravasations or extravasations with effective antidotes available. Do not use hyaluronidase near infected or cancerous tissue for fear of spread. Recombinant hyaluronidase has < 1% incidence of allergy and should not be given to patients who are known to be allergic.

EQUIPMENT

- Syringes, various sizes
- Needles, various sizes
- Antidotes (**Table 141-3**)
- Cold packs
- Warm packs
- Povidone iodine or chlorhexidine solution
- Lidocaine without epinephrine
- Hyaluronidase, 150 units/mL
- Blunt needles
- Scalpel with #11 blade
- Sterile 0.9% saline
- Irrigation basin

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them as an added level of precaution. Mark the area of extravasation with a pen. Take digital photographs if possible.

TECHNIQUES

GENERAL APPROACH TO EXTRAVASATIONS

The general approach to extravasations is noted in this section (**Figure 141-4**).^{3,7,18} Halt the infusion at the first sign of extravasation. Leave the IV catheter in place and do not flush it. Aspirate as much of the extravasate as possible through the IV catheter. Administer analgesics if required. Inject the antidote through the IV catheter and at additional sites as specified for each antidote. Consider a saline washout if a severe extravasation occurs without an available antidote. Remove the IV catheter. Apply dry warm or cold compresses. Warm compresses cause vasodilation which can result in increased systemic absorption, the spread of injury, and increased surface area of the injury. Cold compresses cause vasoconstriction which can concentrate the extravasate, decrease the spread, and worsen the local injury. Apply topical antidotes (e.g., DMSO or nitroglycerin ointment). Elevate the extremity to prevent dependent edema and improve lymphatic outflow. Follow routine wound care with antiseptics (e.g., silver sulfadiazine or topical antibiotic ointment), neurovascular checks, and wound checks. Obtain a consult by a Surgeon per institutional policy and for the development of a compartment syndrome, skin necrosis, and skin ulceration.

SALINE WASHOUT

The saline washout technique can be used for extravasations.^{6,15,16,27} Halt the infusion at the first sign of extravasation. Leave the IV catheter in place and do not flush it. Aspirate as much of the extravasate as possible through the IV catheter. Inject the antidote through the IV catheter and at additional sites as specified for each antidote.

Cleanse the skin with chlorhexidine or povidone iodine solution. Allow the antiseptic to dry. Anesthetize the area of extravasation with subcutaneous lidocaine. Place 1 mL of hyaluronidase (i.e., 150 units/mL) into a tuberculin syringe. The remainder of the procedure can be completed without hyaluronidase if it is unavailable. Inject 0.2 mL of hyaluronidase subcutaneously through the infiltrated IV catheter. **Do not inject hyaluronidase if blood draws from the IV catheter.** Inject an additional 150 units of hyaluronidase through the IV catheter for large extravasations. Inject the remaining hyaluronidase (i.e., 0.8 mL) through a 25 gauge or smaller needle at four points along leading edges of the extravasation. Make four stab incisions with a #11 blade scalpel around the periphery of the extravasation. Insert a blunt needle subcutaneously and manipulate it gently to make subcutaneous tracts. Flush the area of extravasation with 20 to 50 mL aliquots of 0.9% saline solution through each stab incision. Ensure drainage of the saline solution through the remaining incisions. Irrigate a total volume of 500 mL of saline. Continue with routine wound care.

VASOPRESSOR EXTRAVASATION

Stop the infusion when extravasation is detected. Examine the site for signs of toxicity, swelling, or blanching. Leave the IV catheter in place and aspirate to remove as much extravasate as possible. Inject 1 to 2 mg of phentolamine subcutaneously through the IV catheter for significant extravasations. Inject an additional 1 to 2 mg (5 to 10 mg total dose diluted in 10 mL normal saline in adults and 0.1 to 0.2 mg/kg up to 10 mg in children) in four places at the leading edge of extravasation. Terbutaline (1 mg diluted in 10 mL of saline for adults and 0.005 to 0.01 mg/kg in children) can be administered in a similar manner if phentolamine is unavailable. Use 2% nitroglycerin ointment (0.5 to 1 inch in adults and 4 mm/kg up to 1 inch

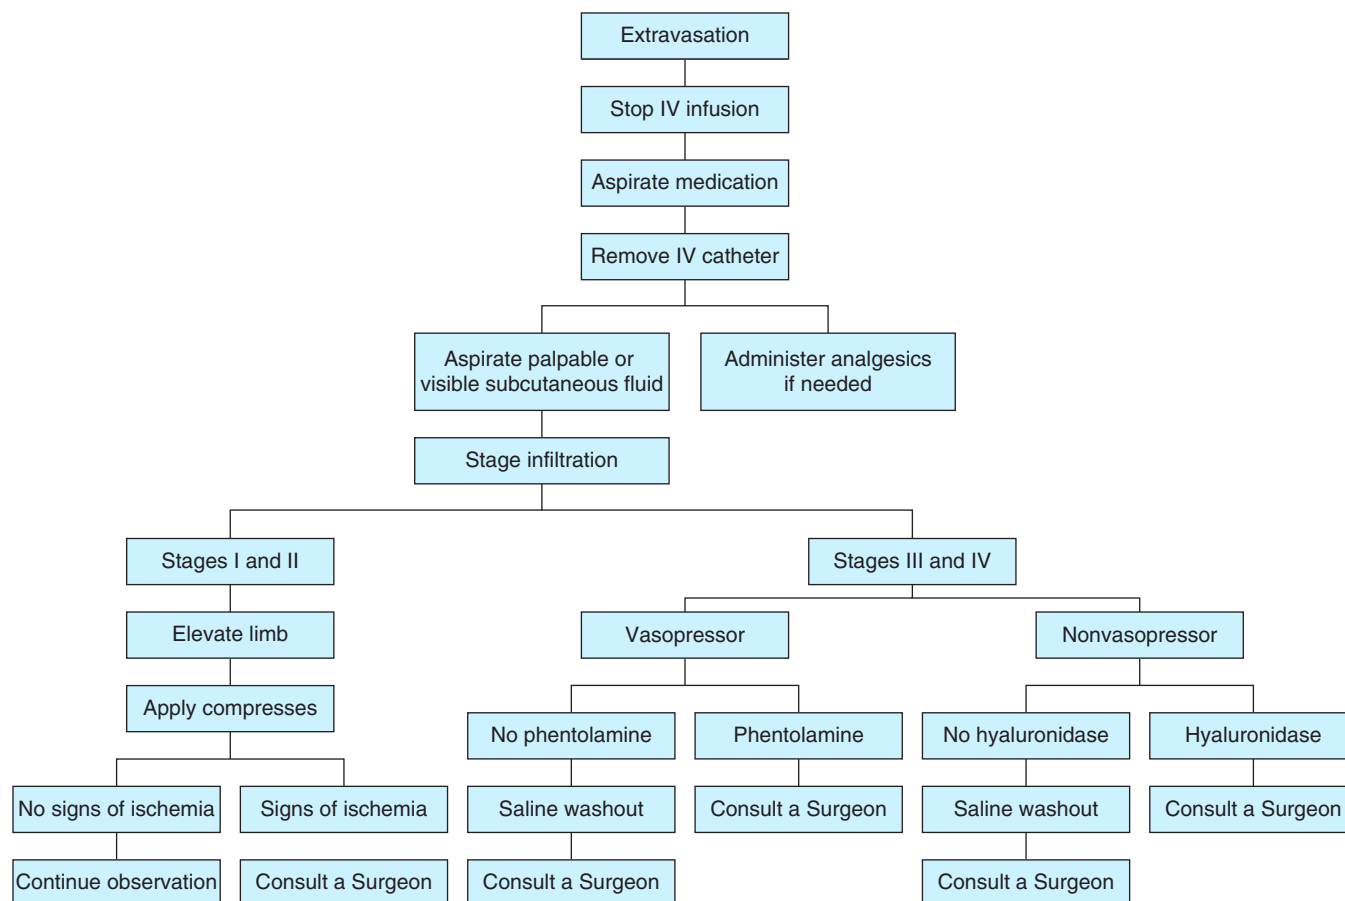

FIGURE 141-4. The general treatment of an extravasation.

in children) applied to the area of extravasation. Similar treatment may be employed for refractory effects of accidental digital epinephrine administration, although patients typically do well regardless of the care given.²⁸ The side effects of phentolamine and nitroglycerin administration include mild hypotension.¹⁷ Continue resuscitation and reinstitute vasopressor therapy at an alternate IV site.

NONNEOPLASTIC MEDICATION EXTRAVASATION

Administration of hyaluronidase can be combined with a washout procedure or it can be used independently. Cleanse the skin with chlorhexidine or povidone iodine solution. Allow the antiseptic to dry. Anesthetize the area of extravasation with subcutaneous lidocaine. Place 1 mL of hyaluronidase (i.e., 150 units/mL) into a tuberculin syringe. Inject 0.2 mL of hyaluronidase subcutaneously through the infiltrated IV catheter. **Do not inject hyaluronidase if blood draws from the IV catheter.** Inject the remaining hyaluronidase (i.e., 0.8 mL) through a 25 gauge or smaller needle at four points along leading edges of the extravasation.³ Some sources recommend dilution of the hyaluronidase solution with saline to 15 units/mL for use in neonates and infants. The package insert does not require this but it may facilitate administering the hyaluronidase over a larger area.

CONTRAST EXTRAVASATION

Treat patients with mild contrast extravasation with extremity elevation, cold or hot packs, and observation for 2 to 4 hours (**Figure 141-3**). They can be managed as outpatients in the absence of a worsening clinical exam. Hyaluronidase as previously described has been used safely for large subcutaneous extravasations but should not be used routinely.²³ Consult a Surgeon for signs of a compartment syndrome. Severe extravasations, severe symptoms, or signs of neurovascular compromise may benefit from hyaluronidase administration.^{18,29} Consult a Surgeon for severe cases and apply silver sulfadiazine for skin blistering and skin ulceration.^{18,29}

CHEMOTHERAPEUTIC EXTRAVASATION

Special attention has been paid to increasing dispersion of extravasations of vinca alkaloids (e.g., vincristine and vinblastine) and epipodophyllotoxins (e.g., etoposide). Use hyaluronidase as previously described and warm compresses. Cold compresses may cause harm. Apply 99% DMSO (or the highest concentration available) topically at the site of extravasation at 4 drops per 10 cm² to an area twice the size of the extravasation every 8 hours for 7 days. Allow the DMSO to air dry. The patient should apply cool compresses for 60 minutes three times a day for 3 days between DMSO applications. This can be accomplished as an outpatient.²⁵

Dexrazoxane is an iron chelator and antidote used for systemic anthracycline toxicity. It has been FDA approved for use in local extravasation injury. Administer IV dexrazoxane within 6 hours at a renally adjusted dose of 1000 mg/m² daily for 2 days and 500 mg/m² on day 3. Discontinue the cool compresses 15 minutes before the administration of dexrazoxane to allow circulation of the antidote to the site. Patients will require monitoring of complete blood counts and liver transaminases following dexrazoxane therapy due to the risk of bone marrow suppression and elevated liver enzymes.^{26,30} Dexrazoxane is costly, specialized, and may not be available. Apply topical DMSO as described previously if dexrazoxane is not available.²⁵

Extravasation of mechlorethamine or high-risk extravasation of cisplatin or bendamustine (e.g., overlying a joint or high concentration or volume) may occasionally occur. This can be deactivated with 4% sodium thiosulfate. Inject 2 mL of thiosulfate per milligram of extravasated agent divided between the extravasated IV catheter and multiple injections around the area of extravasation followed by

intermittent cool compresses for 48 to 72 hours. Sodium thiosulfate at a 4% concentration may be ordered from pharmacy. It may be compounded by mixing 1.6 mL of 25% sodium thiosulfate with 8.4 mL of sterile water or 4 mL of 10% sodium thiosulfate with 6 mL of sterile water. Manage other chemotherapy extravasations with cold packs and general management.^{2,7}

ASSESSMENT

Document any changes due to the extravasation. Note the initial site changes and any further changes. Note the substance extravasated, its concentration, the estimated volume that extravasated, and the circumstances of the extravasation. What were the symptoms of the extravasation and did this change? What size IV catheter was used and what is its length? How was the medication and/or fluid administered (e.g., IV to gravity, IV piggyback, intramuscular pump, or IV push)? Document any problems with the pump if used (e.g., did not alarm) and its serial number. Label the pump for a check by biomedical engineering or the company and set it aside.

AFTERCARE

Document at the time the patient leaves the Emergency Department. Note the extent of injury, the patient symptoms upon leaving, the site of the injury, and any patient comments. Note any patient education. Document all techniques and treatments used on the extravasation. Note the responses, if any, to these techniques and treatments. Document all personnel involved in the patient's care. Most patients will be admitted to the hospital for moderate or severe extravasations. Place patients with mild extravasations in observation. Patients with mild extravasations may be discharged if the patient is reliable and close follow-up can be arranged.

COMPLICATIONS

Most complications are from the extravasation. There are complications associated with treatments. The patient may have an allergic reaction to any treatment antidote. The use of a scalpel to make incisions and blunt needle manipulation can injure arteries, muscle, nerves, tendons, and veins. The use of certain treatments (e.g., nitroglycerine or phentolamine) can result in hypotension. The use of nitroglycerine with the patient using erectile dysfunction medications can result in life-threatening hypotension.

The best way to prevent complications is to prevent the extravasation.^{12,31,32} Ensure that all staff are trained on IV cannula insertion. Start low and move proximally when attempting an IV cannulation. Avoid veins that can cause the IV to dislodge or kink (e.g., antecubital fossa, deep brachial, dorsal hands, and over joints). Do not use small veins or veins used recently. Inject the worst offending medications first. Monitor patients receiving IV infusions. Use caution and extra monitoring in patients with altered mental states, circulatory impairment, confusion, or limited veins.

Other devices may be added for patient safety. The ivWatch (ivWatch, Williamsburg, VA) monitors the IV site to detect leaks, extravasation, and infiltration (**Figure 59-25**). It is comprised of the patient monitor, a reusable sensor cable, single-use disposable sensor applied next to the IV site, and an AC adapter. The monitor gives an audible and visual alert. Refer to Chapter 59 for a discussion of other devices.

SUMMARY

Infiltration of IV catheters is a common occurrence in the Emergency Department. Prevention, conservative management, and good wound care are the cornerstones of management. Washout procedures and antidotal therapy may ameliorate the effects in

severe extravasations or those involving toxic solutions. The level of evidence supporting these therapies is low and the Emergency Physician must determine when they should be employed.

Neurologic and Neurosurgical Procedures

142

Lumbar Puncture

Damali N. Nakitende, Michael Gottlieb,
and Tina Sundaram

INTRODUCTION

Meningitis and subarachnoid hemorrhage (SAH) are serious, life-threatening conditions. They require prompt and accurate diagnosis in the Emergency Department (ED) due to their significant morbidity and mortality.¹ There are many diagnostic modalities available to the Emergency Physician (EP) to assist in the diagnosis. However, the lumbar puncture (LP) is still considered the gold standard. The LP is a procedure that is often performed in the ED to obtain information about the cerebrospinal fluid (CSF) to aid in the diagnosis of a variety of medical conditions. Knowledge about the proper indications, contraindications, various techniques, equipment, and recognition and treatment of potential complications is vital to any EP who performs this procedure. **It is important to perform a thorough neurologic examination prior to the LP, as significant neurologic deficits may suggest increased intracranial pressure (ICP). Significant morbidity and mortality can result if the procedure is performed on the wrong patient.**

ANATOMY AND PATHOPHYSIOLOGY

The entire cavity of the brain and spinal cord has a volume of approximately 1650 mL. CSF occupies only approximately 150 mL of this volume. The brain literally floats in the CSF because the specific gravity of the CSF and brain are approximately the same. Approximately 500 mL of CSF is produced every day. This is approximately 0.35 to 0.5 mL/min. It takes less than 20 minutes for the patient to replace the CSF removed from the LP procedure. Most of the CSF is produced by the choroid plexus within the lateral ventricles. Small amounts of choroid plexus can also be found in the third and fourth ventricles. Lesser amounts of CSF are secreted by the ependymal surfaces of the ventricles. A minimal volume of CSF is produced by the brain through the small perivascular spaces that surround the blood vessels entering the brain substance.

The flow of CSF through the ventricular system is rather simple (Figure 142-1). CSF produced in the lateral ventricles flows through the foramina of Monro into the midline third ventricle. It then passes through the aqueduct of Sylvius into the fourth ventricle. From the fourth ventricle, the CSF flows into the cisterna magna via two lateral openings (foramina of Luschka) and one midline opening (foramen of Magendie). The cisterna magna is located beneath the medulla and cerebellum. It is continuous with the subarachnoid space that surrounds the brain and spinal cord. The CSF then flows through the subarachnoid space to bathe the brain and spinal cord. The CSF is absorbed back into the venous system by way of the arachnoid villi.

The average CSF pressure is 130 mmH₂O when measured in the lateral decubitus position. It can range from 70 to 200 mmH₂O in a normal person after 8 years of age and up to 250 mmH₂O

in the obese patient.² It ranges from 10 to 100 mmH₂O in children up to 8 years of age. The pressure is regulated by the rate of CSF absorption by the arachnoid villi as the CSF production rate is constant. These structures act as one-way valves for CSF to flow into the venous blood of the dural sinuses. Disease states that impede reabsorption can lead to increased ICP.³

Familiarity with the anatomy of the spinal column is important when performing an LP. The anatomy will be briefly reviewed from superficial to deep as the spinal needle traverses the midline structures. The skin and subcutaneous tissue are the first layers encountered. These are followed by the supraspinous and interspinous ligaments, located between the spinous processes of adjacent vertebrae. Deep to these ligaments is the thick ligamentum flavum that accounts for the characteristic “pop” that is described when performing an LP. The next layers encountered are the epidural fat, in the epidural space, followed by the dura mater and finally the subarachnoid space.

There are subtle anatomic differences when considering the lateral approach. The layers include skin and subcutaneous tissue followed by the paraspinal ligaments. The interspinous ligament is less likely to be encountered with an extreme lateral approach, as this is a midline structure. The ligamentum flavum and deeper structures should be encountered in the same fashion regardless of the approach.

INDICATIONS

There are many indications for performing an LP. The primary indications to perform an LP are suspicion of either a central nervous system infection (e.g., meningitis, encephalitis) or an SAH. LP may also be performed for the evaluation of new-onset seizures, to obtain CSF biomarkers, to diagnose and treat idiopathic intracranial hypertension (IIH; formerly known as pseudotumor cerebri), to evaluate for central nervous system diseases (e.g., Guillain-Barré syndrome, multiple sclerosis, systemic lupus erythematosus), to confirm demyelinating or inflammatory diseases, to administer antibiotics or chemotherapeutic agents, to aid in radiologic imaging procedures (e.g., cisternography or myelography), or to diagnose meningeal carcinomatosis.

SUSPICION OF MENINGITIS IN ADULTS

An LP should be performed in adults when there is a clinical suspicion of a central nervous system (CNS) infection.⁴ The absence of fever does not exclude a CNS infection. Meningeal signs include nuchal rigidity, Kernig's sign, and Brudzinski's sign. Other signs of a possible CNS infection include a severe headache, photophobia, or a petechial rash. Many of these signs may not be present. This is especially true in elderly, young, or immunocompromised patients. **An LP should be strongly considered in febrile adults with an altered mental status and no alternate source of fever.**

Two commonly cited meningeal findings include the Brudzinski's sign and the Kernig's sign (Figure 142-2). Both tests are performed in the supine patient. For the Brudzinski's test, passively flex the

FIGURE 142-1. CSF circulation around the brain and upper spinal cord.

patient's head until their chin touches the sternum. Flexion of the patient's hips and knees in response to the head flexion is considered a positive Brudzinski's sign (**Figure 142-2A**). The patient may also experience neck pain and resistance to flexion if meningitis is

present. For the Kernig's test, passively flex one of the patient's legs to 90° at the hip and to 90° at the knee (**Figure 142-2B**). Passively extend the knee. Pain in the lower back or resistance to knee extension is known as a positive Kernig's sign.⁵ Neither test is very sensitive or specific for meningitis.⁶

FIGURE 142-2. Physical examination of meningeal signs. **A.** Brudzinski's sign. Upon passive elevation of the head, the patient complains of neck and low back pain and may have involuntary flexion of the knees and hips suggesting meningeal irritation. **B.** Kernig's sign. Begin with the patient starting in a supine position with their hips and knees flexed 90°. Gradually extending the knee causes the patient to complain of neck or lower back pain.

SUSPICION OF MENINGITIS IN CHILDREN

The decision of whether to perform an LP on a febrile infant is based on the clinical suspicion of meningitis, the age and appearance of the child, and whether an identifiable source of fever is present.⁴ The EP will often be faced with a well-appearing febrile infant with no obvious source of fever. In the past, many institutions managed all febrile infants less than 3 months old with a full sepsis evaluation, to include an LP and admission to the hospital. Newer recommendations suggest that the full septic evaluation is now indicated for infants less than 1 month old and strongly considered in infants less than 60 days old.

Guidelines are available to identify patients at low risk for serious bacterial infection, where LP and hospitalization may or may not be indicated.⁷ Examples of serious bacterial infections include meningitis, sepsis, osteomyelitis, septic arthritis, urinary tract infections, pneumonia, and enteritis. The clinical evaluation alone is inadequate to exclude serious bacterial infections in infants. It must be combined with laboratory studies that help to define low-risk criteria. These criteria only apply to non-toxic-appearing infants with reliable parents and follow-up. A more detailed discussion regarding the evaluation of the child with a fever is beyond the scope of this chapter.

It should be noted that any febrile child, regardless of age, who appears "toxic" should have an LP as an integral part of the sepsis evaluation. Certain bacterial infections have a high propensity for dissemination and systemic bacteremia. Examples include epiglottitis, buccal cellulitis, periorbital cellulitis, and septic arthritis. These children should be considered for an LP as part of their evaluation depending on the clinical scenario.

IS AN LP INDICATED FOR THE FIRST FEBRILE SEIZURE?

The EP will be faced with the decision of whether to perform an LP when evaluating infants and children with a first febrile seizure. The American Academy of Pediatrics (AAP) recommends that an LP should be performed for any child if there is a clinical suggestion of meningitis.⁸ Clinical signs and symptoms that have been shown to correlate with the presence of meningitis include petechiae, nuchal rigidity, coma, persistent drowsiness, Kernig's or Brudzinski's sign, status epilepticus, and paralysis.⁹ The AAP also recommends performing an LP if the child has not received their *Haemophilus influenzae* type b (Hib) immunization or *Streptococcus pneumoniae* immunization, or if the immunization status cannot be determined.⁸

Benign febrile seizures are those that occur in children 6 through 60 months of age, are associated with a fever at the onset of an illness, and involve a single generalized seizure lasting less than 15 minutes in a child that did not recur within 24 hours.⁸ **These children generally appear well except for the fever and usually do not require an LP.**

Complex febrile seizures are those that do not meet the criteria of a benign febrile seizure. These children require a complete septic evaluation including an LP. Criteria include seizures that begin focally, seizures lasting over 15 minutes, children with a prolonged postictal period, suspicious findings on physical examination, children less than 6 months of age, children already receiving antibiotics, or children who have had multiple seizures during a single period of illness. Suspicious findings on physical examination that suggest a complex seizure include rashes, petechiae, cyanosis, hypotension, abnormal respirations, increased or floppy tone, stiff neck, difficult to console, deviated eyes, doll's eyes, nystagmus, ataxia, photophobia, bulging or tense fontanelles, eyes that are unable to fix and follow, and no response to voice or painful stimuli.

SUBARACHNOID HEMORRHAGE

A suspected SAH is the other common indication for an LP.¹⁰⁻¹⁷ The classic description of an SAH is the sudden onset of an excruciating headache (often described as a "thunderclap" headache) during exertion that may or may not be associated with syncope, nausea, vomiting, diaphoresis, or meningeal signs. Physical examination findings may include nuchal rigidity, an altered level of consciousness, papilledema, retinal hemorrhage, third-nerve palsy, sixth-nerve palsy, bilateral lower leg weakness, nystagmus, ataxia, aphasia, or hemiparesis. Additional risk factors for a SAH include cigarette smoking, hypertension, alcohol abuse, a family history of SAH, polycystic kidney disease, connective tissue disorders, or sickle cell anemia.

It is estimated that 20% to 50% of patients with an SAH may have sentinel bleeds that precede the major bleeding event. **It is important to diagnose a sentinel bleed because early management and intervention can improve the overall outcome for the patient. A sentinel bleed may precede a major SAH by hours, days, weeks, or months.**^{18,19}

A computed tomography (CT) scan of the head is often the first study used to investigate a patient complaining of a sudden-onset headache concerning for SAH.²⁰ The small volume from a sentinel bleed into the subarachnoid space diffuses and is diluted away from the source and hemolyzes. The sensitivity of CT scan for SAH can range from 92% to 98% when performed within 24 hours of the onset of symptoms.²¹⁻²³ The sensitivity decreases markedly when performed 48 to 72 hours after onset of symptoms.^{24,25} The head CT scan can be negative in the patient with a sentinel bleed. The head CT scan can be negative in the patient with anemia.

Should an LP be performed if the CT is negative? This issue is currently debated and controversial. The sensitivity of CT scanners is increasing. Some have suggested that the LP can be omitted if the head CT is negative within 6 hours of the headache onset due to the low incidence of positive LPs.²⁶⁻³² There is not enough evidence now to justify not doing an LP. Performing an LP in this group of patients may become unnecessary in the future.³³

An LP must be performed if the CT scan is negative and an SAH is still suspected.^{14-17,20,30} The presence of either xanthochromia or red blood cells in the CSF will confirm the presence of bleeding. While the CSF will usually confirm an SAH, it is possible that the LP may be negative despite a recent SAH if there has not been sufficient time for the red blood cells to migrate to the lumbar spine area. In this case, despite a negative head CT scan and a negative LP, a cerebral angiogram or follow-up LP in 12 to 18 hours should be performed.

CONTRAINDICATIONS

Knowledge of the contraindications to performing an LP is important.³⁴ The EP will often have to weigh the potential risks of performing the procedure with the benefits of obtaining the CSF. The decision must be made whether the procedure should be performed immediately or can be delayed until further studies are completed. Absolute contraindications to performing an LP include a cellulitis or abscess at the skin puncture site or signs and symptoms of increased ICP (except for IIH). The LP should be delayed in patients with an unstable airway, hypotension, shock, or status epilepticus until the patient has been stabilized. Relative contraindications to performing an LP include the presence of a brain abscess, epidural or subdural fluid collection, brain tumors, and spinal cord tumors.

Note that antibiotics should not be delayed if meningitis is suspected and the LP must be delayed.^{35,36} **If meningitis is highly suspected and the patient is unstable, treatment should be initiated with parenteral antibiotics and steroids. The LP can be delayed until the patient's condition is stabilized.**

Do not perform an LP if the patient has an intrathecal pump. An LP can damage the catheter, even if going inferior to the scar. The catheter can loop below the scar and be damaged by the spinal needle. Consult an Interventional Radiologist to perform the LP under fluoroscopy.

INCREASED ICP

An LP is relatively contraindicated in the presence of increased ICP.^{34,37-39} This includes patients with space-occupying lesions (e.g., tumor or abscess), lateralizing signs (e.g., hemiparesis), or when signs of uncal herniation are present (e.g., unilateral third-nerve palsy). Brain herniation or coning has been reported in patients with meningitis and increased ICP due to the sudden drop in spinal pressure induced by the removal of CSF from the LP.

IIH has been treated with a combination of medicines and repeated LPs to lower ICP. Removal of CSF for IIH is a common diagnostic and therapeutic procedure in the ED. The performance of an LP for IIH in the ED is controversial. Many of these patients are obese, which can make an LP more difficult to perform, require multiple attempts, and be painful for the patient. The CSF removed reforms within a few hours. The LP provides only temporary relief of the patient's symptoms. It is recommended to consult a Neurologist before performing an LP in the patient with a known diagnosis of IIH. An LP may be required to make the initial diagnosis of IIH but may be unnecessary in the patient when the diagnosis has been made previously.

BRAIN ABSCESS

Patients with a brain abscess are at high risk for herniation.^{34,40,41} Brain abscesses may present with a progressively worsening headache, low-grade fever, or the development of focal neurologic signs (e.g., hemiparesis, papilledema, visual field deficits, and mild obtundation). Suspect a brain abscess in patients with a history of otic or paranasal sinus infection, orbital cellulitis, chronic pulmonary or intraabdominal infection, endocarditis, congenital heart disease, recent dental procedures or abscesses, recent neurosurgery, craniofacial trauma, open skull fractures, or recent meningitis.

WHEN IS A CT SCAN INDICATED BEFORE AN LP?

Increased ICP by itself is not necessarily a contraindication to an LP. ICP is usually mildly elevated in patients with IIH or meningitis.^{34,42-44} A CT scan does not need to be routinely performed in straightforward cases of suspected meningitis when the patient has a normal neurologic examination. The inability to visualize the optic discs does not constitute a focal finding and, by itself, is not an indication for a head CT scan prior to an LP.⁴⁵ Despite this, there are occasional cases of herniation in patients with a normal CT scan.^{37,38,43}

Most literature suggests that CT scans be performed prior to LP when patients are comatose or altered, have focal neurologic signs, are human immunodeficiency virus (HIV) positive, have a progressively worsening headache, or have papilledema.^{34,45-47} **The lack of papilledema is not always a reliable sign of normal ICP, as it often takes greater than 48 hours to develop papilledema.**⁴⁸ Papilledema may be absent in up to 15% of adults and up to 50% of children with early increased ICP.

The CT scan should be evaluated for mass lesions, shift of midline structures, or hydrocephalus due to obstructing masses, cisternal obstruction, and cerebral edema.^{34,47} There are three findings that may predispose a patient to herniation if an LP is performed.⁴⁹ The first finding is midline shift. This suggests unequal pressures across the midline. The second finding is loss of the suprachiasmatic and basilar cisterns. This suggests unequal pressures between the supratentorial and infratentorial compartments. The third finding is any evidence of a posterior fossa mass, obliteration of the superior cerebellar cistern, or obliteration of the quadrigeminal plate cistern which lies caudal to the midbrain. These findings all suggest the presence of increased infratentorial pressure.

Do not delay the initiation of antibiotics if meningitis is suspected and a CT scan is indicated before performing an LP.^{35,36} **Administer the antibiotics and steroids before the patient undergoes CT scanning.** Several studies have shown that delays in the initiation of antibiotics are common in the ED. These delays are often EP generated and result from the need for a CT scan prior to LP, waiting for LP results before administering antibiotics and steroids, and not giving antibiotics and steroids before a patient is transferred to the ward.⁵⁰⁻⁵³

COAGULATION ABNORMALITIES

An LP is relatively contraindicated in patients with a coagulopathy.³⁴ This includes hemophiliacs, those on anticoagulants, and patients with thrombocytopenia. An LP can result in a spinal epidural or subdural hematoma with subsequent spinal cord compression. Appropriate replacement of platelets, replacement of clotting factors, and/or administration of reversal agents should be undertaken prior to attempting an LP if the procedure can be delayed.⁵⁴⁻⁵⁶ **The most experienced EP should perform the procedure with a small-gauge needle when an immediate LP is indicated in these patients.**

BACTEREMIA

Some sources list bacteremia as a contraindication to an LP, especially in children. While there is some suggestion that there may be an association between performing an LP in a bacteremic patient and the later development of meningitis, the risk of this is low. **An LP should not be withheld for fear of inducing meningitis in these patients.** The risk of delaying the diagnosis of meningitis clearly outweighs the small chance of causing meningitis with an LP.⁵⁷

EQUIPMENT

- Sterile gloves and gown
- Face mask and cap
- 1% lidocaine solution
- Povidone iodine or chlorhexidine solution
- LP needles, various gauges and lengths
- Topical anesthetic agent (e.g., eutectic mixture of local anesthetics [EMLA]), optional
- LP kit

Most of the equipment necessary for performing an LP is available in prepackaged, sterile, disposable, and single patient use commercial kits (**Figure 142-3**). These kits usually contain a 20 gauge Quincke spinal needle, syringes, needles (e.g., 25 gauge and 22 gauge) for local anesthesia, a manometer with a stopcock, sterile drapes, specimen tubes, 1% lidocaine, gauze, brushes for prepping the skin, and a bandage. Some kits provide povidone iodine or chlorhexidine swab sticks, whereas other kits have a small basin that needs to be filled. The EP should become familiar with the kit used at their institution.

Additional supplies may be needed to perform the procedure without interruption. For example, some EPs prefer a smaller gauge Quincke needle or a nontraumatic needle such as a Sprotte or Whitacre which are not often provided in the commercial kits (**Figure 142-4**). The use of a 25 gauge spinal needle is recommended as it causes a smaller puncture hole and a lower risk of postprocedural headache.⁵⁸⁻⁶² It has been suggested that atraumatic needles should be the standard when performing an LP.^{63,64} It is a good idea to have extra spinal needles, lidocaine, gauze, and skin antiseptic (e.g., povidone iodine or chlorhexidine solution) when performing an LP. There are numerous formulae to determine the LP depth and the length of the spinal needle required.^{65,66} A reliable formula for

FIGURE 142-3. A commercially available LP kit.

FIGURE 142-4. The three types of spinal needle tips. The standard Quincke needle has a sharp, beveled end. The Whitacre and Sprotte needles are designed to spread atraumatically, rather than cut dural fibers.

estimating the required LP needle length is $\text{LP depth (cm)} = 1 + [17 \times (\text{weight [kg]} \div \text{height [cm]})]$.⁶⁶

There are subtle differences among the spinal needles commonly available (**Figure 142-4**). The standard Quincke needle has a sharp tip with a broad bevel at the end. The Whitaker and Sprotte needles have smaller tips with smaller diameter bevels. The bevel of the

Sprotte needle is broader with a rounded tip to separate the fibers of the dura as opposed to cutting through them. **Always remember to keep the bevel oriented parallel to the fibers of the dura when performing an LP regardless of needle style.**

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Include the post-LP headache, its occurrence, and its treatment.⁶⁷ Obtain an informed consent for the procedure and place this in the medical record.⁶⁸ When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.⁶⁹ Ask the parents or caregivers if they would like to be present for the LP.

There are a variety of different patient positions that can be used to perform the LP (**Figure 142-5**).^{58,70,71} Knowledge and proficiency in more than one approach will be useful for the EP when encountering a difficult LP. The position of the patient will be chosen based upon the patient's body habitus, their ability to assume a position, their level of cooperativeness, and EP preference.

The sitting position is more commonly used in adults than the lateral decubitus position. It is easier to identify the midline and

FIGURE 142-5. Patient positioning for an LP. **A.** An adult in the sitting position. **B.** An adult in the lateral decubitus position. **C.** An infant restrained in the sitting position. **D.** A child held in the sitting position. **E.** A child held in the lateral decubitus position.

palpate the spinous processes with the patient sitting (**Figure 142-5A**). The sitting position is particularly useful when patients are obese. While the LP can still be performed in the lateral decubitus position for obese patients, palpating the spinous processes and identifying the midline can be difficult. **The measurement of hydrostatic pressure in the CSF is not accurate with the patient sitting, as it can give a falsely elevated pressure reading.**

The lateral decubitus position is often the most comfortable position for the patient (**Figure 142-5B**). Place the patient with their knees flexed and the upper back curled forward to widen the interlaminar spaces. Ensure that the patient's shoulders, back, and hips are exactly perpendicular to the stretcher and floor. This will increase the chances of keeping the needle in the midline as it is introduced parallel to the surface of the stretcher. This is particularly important in infants and children where an assistant may be called upon to hold the patient in position. **Severe neck flexion is not necessary and can lead to airway obstruction or lack of CSF flow.**

Children can be placed in the sitting or lateral decubitus position.^{72,73} An assistant can easily maintain neonates and infants in the sitting position (**Figure 142-5C**). Toddlers and school-aged children can often be maintained in the sitting position (**Figure 142-5D**). The lateral decubitus position can be used for any child (**Figure 142-5E**).⁷⁴ **It is important to assess the child visually and with pulse oximetry during the procedure.**⁷⁴ These positions may cause improper neck flexion that can result in respiratory compromise, oxygen desaturation, hypoxemia, and anoxic encephalopathy.^{75,76} **The largest interspinous space is achieved with the patient sitting upright with their hips flexed, leaning forward, and with slight neck flexion based on ultrasonographic studies.**⁷⁶⁻⁷⁹

The subarachnoid space must be entered below the termination of the spinal cord that is situated at the lower level of L1 or the body of L2 (**Figure 142-6**). Identify by palpation the vertebral spinous processes in the midline and the posterior superior iliac spines. The patient can help to determine if the needle is in the midline by providing real-time feedback of where they feel the needle.^{80,81} Just ask them if the needle is in the midline. Another option is to draw a line between the spinous process of C7 and the gluteal cleft.⁸² An imaginary line connecting the posterior superior iliac spines (i.e., Tuffier's line) should intersect the midline at approximately the L4 spinous process or the L3-L4 interspace. **One can select any of the spaces between L2-L3 and L5-S1 to perform an LP.** Palpate the intended interspace before prepping the area. Some EPs mark the site lightly with a pen or make a small indentation with the hub of a needle. Adjust the bed height so that you can sit in a comfortable position while performing the procedure.

Prepare the LP kit. Open the kit using sterile technique and place it on a bedside table. Place povidone iodine or chlorhexidine solution into the basin provided with the kit. Place any additional needles or supplies onto the sterile field. **This procedure requires strict aseptic technique. The EP should don full sterile and personal protective equipment at this point.**⁸³⁻⁸⁵ This should include sterile gloves, a sterile gown, a face mask, and a cap. Prepare the stopcock and manometer. The manometer is usually in two pieces that slide together. Insert the manometer into the vertical port of the stopcock. Turn the handle toward the outflow side of the stopcock. The stopcock handle will occlude the port that it points to. Pull the stylette out of the spinal needle to ensure there is no damage.⁸⁶ Replace the stylette into the spinal needle.

Prepare the patient's back. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution using a circular motion from the intended site of entry outward. Allow the solution to completely dry prior to inserting the spinal needle.⁸⁷ Chlorhexidine solution introduced into the spinal canal can result in arachnoiditis and neurotoxicity.⁸⁸ Avoid chlorhexidine solutions

FIGURE 142-6. Midsagittal section of the lumbosacral region with a spinal needle in the L3-L4 interspace. The needle has penetrated the supraspinous ligament, the interspinous ligament, the ligamentum flavum, the dura mater, and the arachnoid mater.

above 0.5%.⁸⁷ Prepare an area of at least 10 cm in diameter. Most kits include a solid drape and a fenestrated drape. Place the solid drape between the patient's hips and the bed. Place the fenestrated drape with the adhesive side toward the patient's back and the opening centered at the desired level for the procedure.

Reidentify the anatomic landmarks. Place a finger over the desired interspace to use for the procedure. Place a skin wheal of local anesthetic solution subcutaneously over the desired interspace using a 25 gauge needle. Infiltrate and anesthetize the deeper tissue of the interspace along the projected needle track using the 22 gauge needle. **The infiltration of local anesthetic solution, unless contraindicated, should be used in all patients, including neonates and young children.** Local anesthetic makes it more likely the LP will be successful.^{77,78,89}

Alternatively, a field block can easily be performed to produce anesthesia of the skin, interspinous ligaments and muscles, and the periosteum. The interspinous ligament and the periosteum are supplied by the recurrent spinal nerves branching off the nerve roots exiting the spinal canal at the same level. Inject local anesthetic solution into the interspinous ligaments, between the spinous processes superior and inferior to the intended puncture site, and on either side of the interspinous space (**Figure 142-7**).⁵⁸ A topical anesthetic (e.g., EMLA cream) may be applied over the interspace for 30 to 60 minutes prior to performing the LP if the patient is awaiting a CT scan of the head and antibiotics have been administered. The topical anesthetic only anesthetizes the skin and superficial subcutaneous structures. The patient will still require an anesthetic injection. A jet injector (Chapter 154) can be used to deliver the local anesthetic.^{90,91}

FIGURE 142-7. Field block for LP anesthesia.

It may occasionally be difficult for some patients to remain still and cooperative with the procedure. This can include anxious patients, those with an altered mental status, and small children. These patients may require an intravenous anxiolytic, nitrous oxide administration (Chapter 158), or procedural sedation (Chapter 159).

TECHNIQUES

LATERAL DECUBITUS POSITION AND MIDLINE APPROACH

Palpate the intended interspace. Introduce the needle in the middle of the interspace and parallel to the bed. **Orient the bevel of the spinal needle parallel to the longitudinal dural fibers to increase the chances that the fibers will be separated rather than cut by the tip of the needle.**⁹² This has been shown to decrease the incidence of postdural puncture headache.⁹³⁻⁹⁵ The bevel should point up or down with the patient in the lateral decubitus position. Angle the needle 10° cephalad, or toward the umbilicus, and advance it slowly. The needle can be held between both index fingers and advanced with the thumbs (**Figure 142-8A**). Alternatively, it can be guided with a thumb and forefinger near the puncture site while the other hand holds the hub of the needle and advances it (**Figure 142-8B**).

Resistance will usually be felt as the needle penetrates the interspinous ligaments. Stop advancing the needle and remove the stylet frequently to check for the presence of CSF.⁹⁶ Many describe a characteristic “pop” that is felt when the needle enters the subarachnoid space. The commonly used Quincke needles often decrease or eliminate this sensation.⁹⁶ If bone is encountered, withdraw the needle to the subcutaneous tissue, confirm your landmarks, and readvance the needle in the midline. If bone is still encountered, redirect the needle slightly more cephalad and readvance it. Perform the procedure at a different level if still unsuccessful.

CSF should flow freely once the subarachnoid space is entered. The rate of CSF flow from the hub of the spinal needle may be slow. The flow rate can be increased by one of the following: ask the patient to Valsalva by gently coughing or bearing down, rotate the spinal needle 90°, or repeat the procedure with a larger bore

FIGURE 142-8. Two-handed techniques for spinal needle insertion. **A.** The index fingers guide the tip while the thumbs advance the needle. **B.** An alternative technique. One hand is placed at the needle tip and the other is at the base of the needle.

spinal needle. Attach the stopcock and manometer directly to the needle or use the short extension tubing provided in most kits as a spacer. **Hold the hub of the needle firmly between the thumb and index finger and brace your hand against the patient’s back when attaching or removing anything from the spinal needle.** This will prevent the needle from advancing or withdrawing. The stopcock handle should point posteriorly, allowing CSF to fill the manometer.

Ensure that the manometer hub remains at the level of the needle in order to get an accurate reading if using the extension tubing. Phasic changes with respirations should be noted as the manometer fills. Instruct the patient, or an assistant, to gently extend the patient’s legs to decrease intraabdominal pressure and lower the reading. Normal opening pressure ranges from 70 to 180 mmH₂O in most patients. Obtain the pressure reading once the CSF flow stops. Turn the stopcock handle toward the needle hub (i.e., the patient) to empty the contents of the manometer into the

first tube for collection. To continue collection, remove the stopcock or simply remove the manometer and continue collection through the stopcock by pointing the handle toward the manometer port.

In general, 1.0 mL of CSF in each of the four tubes should be adequate to perform the CSF analysis. Collect 2 mL in each tube if cytology or antigen testing is necessary. The rate of CSF collection can be increased. Ask the patient to cough or bear down (e.g., as in doing a Valsalva), instruct an assistant to push on the patient's abdomen, turn the spinal needle 90°, or use a larger diameter spinal needle to increase the flow of CSF. **Carefully replace the stylet and remove the needle when the samples have been collected.**

There is disagreement regarding the use of the spinal needle stylet.⁹⁷ The literature notes an increased incidence of intraspinal epidermoid tumors after an LP if a stylet is not used. This led to the habit of leaving the stylet in place while inserting the spinal needle to prevent transferring epidermal cells into the spinal canal. Some experts now recommend removing the stylet after the tip of the spinal needle has been inserted past the epidermis.^{77,98} This method has been shown to result in a greater success rate when performing an LP.

Reinserting the stylet into the spinal needle is potentially problematic. Many will hold and stabilize the spinal needle with one hand and reinsert the stylet with the other hand. This risks a potential needlestick injury. The book editor inserts the tip of the stylet with one hand without using the other hand to stabilize the spinal needle. Once the stylette is partially inserted, grasp the spinal needle with the other hand and fully insert the stylette. This prevents punctures by the stylette. Reinserting the stylet prior to removal of the spinal needle has been shown to decrease the incidence of the post-LP symptoms of dizziness, headache, nausea, and tinnitus.⁹⁹ The method of using the stylet is left to EP preference.

SITTING POSITION AND MIDLINE APPROACH

Place the patient sitting on the edge of the bed. Ask the patient to flex their lower back and lean forward onto some support (e.g., an assistant or bedside stand) to open the interlaminar spaces in the lumbar area. Orient the bevel of the needle laterally (i.e., to the left

or right). The remainder of the procedure is the same as previously described.

LATERAL APPROACH

The lateral approach may be useful in avoiding the calcified supraspinous and interspinous ligaments often encountered in elderly patients. This approach may be performed with the patient in the lateral decubitus position or the sitting position. Although it is less commonly used than the midline approach, it is a good idea for the EP to become familiar with this technique as an alternate approach if the midline approach has failed. This may prove easier in the patient who has had multiple previous midline LPs.

Position the patient and select an appropriate interspace. Cleanse, drape, and anesthetize the area as previously described. Insert the spinal needle 1.5 to 2.0 cm lateral to the midline. The needle can approach from either side (i.e., left or right) if the procedure is being performed in the sitting position. Approach from the inferior side if performing the LP in the lateral decubitus position (**Figure 142-9A**). Direct the needle 10° cephalad and approximately 20° to the midline. This angle will direct the needle through the erector spinae muscles and lateral to the supraspinous and interspinous ligaments. The needle will penetrate the ligamentum flavum, the dura, and then the subarachnoid space (**Figure 142-9B**). If bone is encountered, partially withdraw the needle and redirect it at the same angle toward the midline but slightly more cephalad. The remainder of the procedure is as described previously.

LP IN INFANTS AND CHILDREN

Performing an LP in an infant or child is similar to that of an adult. Place the patient in the lateral decubitus position or the sitting position.^{72,73,100} Place the neck in mid-flexion in the lateral decubitus position. **Severe flexion of the neck does not facilitate the procedure and can result in lack of CSF flow or airway obstruction.**

Hypoxemia has been reported during LP in infants. The increased intraabdominal pressure caused by flexing the knees

FIGURE 142-9. The lateral approach. **A.** The patient is in the lateral decubitus position. Insert the spinal needle approximately 2 cm below the midline, directed approximately 20° toward the midline and 10° cephalad. **B.** Cross-section of the spinal column showing the path of the spinal needle during the lateral approach. Notice that it avoids the calcified supraspinous and interspinous ligaments.

into the abdomen may lead to compression of the diaphragm, ventilation-perfusion mismatch, and hypoxemia.¹⁰¹ The sitting position or modified lateral decubitus position (e.g., hips only flexed to 90°) is preferred.¹⁰² Preoxygenation with 100% oxygen via face mask for 2 to 5 minutes may prevent hypoxemia.¹⁰³ **Consider the use of continuous pulse oximetry in infants and young children undergoing an LP.**

Some authors advocate the use of a butterfly needle and using the tubing as a manometer to get a general idea of the opening pressure. The use of nonstyletted needles, however, may occasionally result in the implantation of cells and a subsequent epidermoid tumor. In some low ICP syndromes, CSF may fail to flow during the procedure and gentle suction with a 1 mL syringe can be used.

Local anesthesia should be used in all patients, including neonates. There is evidence that pain perception is present even in premature neonates.¹⁰⁴ The use of local anesthetic is often omitted in the neonate and young infant, possibly in fear of obscuring anatomic landmarks. The success rate of LP in neonates given local anesthetic, the amount of struggling during lidocaine injection, and the amount of struggling during spinal needle insertion were studied.¹⁰⁵ The study found that local anesthesia did not alter the success rate of the procedure and led to a decreased amount of struggling during spinal needle insertion.

The use of EMLA cream or similar topical anesthetic is common and effective for venipuncture in children. It also can be used successfully before LP in children and adults (Chapter 154).^{106,107} In some studies on adults, EMLA has been shown to be more effective than lidocaine infiltration.^{108,109} The major disadvantage of EMLA cream is that it requires application for a minimum of 30 minutes before the procedure is performed. It is more effective if it stays on longer. It does not anesthetize the deeper tissues and local infiltration is still required.

Procedural sedation is usually reserved for children getting routine LPs for intrathecal chemotherapy. Procedural sedation can be used while performing a diagnostic LP. Procedural sedation should not be used unless the child has a normal mental status and is hemodynamically stable. The decision regarding procedural sedation should be considered on a case-by-case basis.

The angle of the spinal needle insertion was found to be different in different age groups.¹¹⁰ The angle was more acute in infants compared with younger children. It remains to be seen whether this clinical difference affects the success rate of an LP.

ULTRASOUND-GUIDED LP

Anesthesiologists have been using ultrasound (US) to assist in various spinal procedures. EPs have reported on the use of US to assist in performing an LP or to evaluate spinal anatomy.¹¹¹⁻¹²³ US-guided LP was performed easily and was successful in patients in whom multiple attempts at landmark-guided LP were unsuccessful.¹¹³ The authors concluded that the technique has great potential as a time-saving tool. A randomized, double-blind study compared LP using landmarks identified by palpation versus those identified by US.¹¹⁵ The use of US significantly reduced the number of failures in all patients and improved the perceived ease of the procedure in obese patients. A group of Radiologists studied US guidance for LPs in children.¹²⁴ They found US superior to fluoroscopy as it allowed three-dimensional guidance in real time and provided visualization of soft tissue structures.

US is more readily available in EDs to assist the EP in performing many procedures including an LP.^{111,112} US can visualize superficial and deep tissue structures. EPs who consider using US in assisting with an LP should be properly trained in the use and theory behind US before attempting to use it in the clinical setting.

There are three possible approaches to establishing the indications for the use of US to guide an LP. US guidance could be used for an LP when the traditional landmark-guided approach has failed. This approach may result in more patients having multiple attempts at an LP. US guidance could be used as the initial method in patients predicted to have a higher failure rate with landmark-guided LP with spinal landmarks that are difficult or impossible to palpate.^{112,125,126} These include patients in whom the landmarks are increasingly difficult to palpate as a result of being in the body mass index (BMI) categories of overweight (BMI 25 to 29.9) and obese (BMI ≥ 30).¹¹¹ Patients in whom an LP is not predicted to be difficult would have it attempted initially with the landmark palpation method, reserving US guidance for failures. The final approach uses US guidance initially for all patients, regardless of their BMI or the predicted ease of an LP.

US can be used to visualize the anatomic structures and mark the point of needle insertion. It can also be used to visualize the deep soft tissue structures, allowing the EP to estimate the depth that the needle needs to be inserted to enter the subarachnoid space. Using US to identify landmarks improves success rates, decreases the number of attempts, and decreases the number of traumatic LPs.^{120,127-131} The use of US may decrease the hospitalization rate for traumatic or unsuccessful LPs.¹³²

A high-frequency linear US transducer in the range of 5 to 10 MHz is the transducer of choice. The linear transducer may not allow visualization to the depth required in patients with a higher BMI. Use a lower frequency US transducer (e.g., a curvilinear array abdominal transducer in the range of 2 to 4 MHz). A pen or surgical skin marker is needed to mark the skin at the point of needle insertion. Surgical skin markers have the advantage of using scrub-resistant, nonsmearing ink.

Transverse and longitudinal midline images centered over the lumbar spine are used.^{111,112} There is a preference for the paramedian longitudinal view.¹¹² This view was felt to allow better visualization of deep soft tissue structures such as the ligamentum flavum and dura mater. The spinous process causes a shadow that extends from near the top to the bottom on the monitor screen in the transverse view (**Figure 142-10**).^{113,125} The distal tips of the spinous processes are seen as a series of echogenic convexities in the longitudinal view (**Figure 142-11**).¹¹⁷

Place the patient into the position they will be in during the LP, whether the lateral decubitus position or sitting upright. It is important that the patient be in the exact position (e.g., with spinal flexion and their knees drawn up) that will be used during the LP. **Any change in patient position between the time of the US and the LP could change the location of the landmarks and decrease the likelihood of success.**

Use US to locate the entry site of the spinal needle. Use the transverse view at the level of the iliac crests and move the US transducer until the shadow caused by the spinous process is centered on the monitor screen (**Figure 142-10**). Use the skin marker to place a mark on each side of the transducer at its midpoint (**Figure 142-12**). The two lines are connected and will form a single line that marks the midline of the spine. Rotate the US transducer 90° to a midline longitudinal view. Move the US transducer until the tops of two adjacent spinous processes are seen with the gap between them located in the center of the screen (**Figure 142-11A**). Again, make two marks on the patient's skin, one on each side of the US transducer at its midpoint (**Figure 142-13**). These two marks are connected to form a single transverse line that indicates the center of the gap between adjacent spinous processes. Color flow Doppler can be used to visualize the vascular structures and help decide the location of the LP.¹¹⁸

US can be used to measure the depth to the CSF and the depth of spinal needle insertion. This can guide the EP more than

FIGURE 142-10. US image of the lumbar spine in the transverse view. The spinous process (arrow) causes a shadow that extends from the top to the bottom of the monitor screen.

the equations. US answers the question of how deep to insert the spinal needle.

Set aside the US transducer. Connect the two pairs of skin marks to form two lines that intersect at a right angle (**Figure 142-14**). Their intersection marks the site of needle entry (**Figure 142-14**). Clean and prep the patient's skin and perform the LP as described previously.

RISK FACTORS FOR TRAUMATIC OR UNSUCCESSFUL LP

There are numerous risk factors for obtaining a traumatic or unsuccessful LP.^{98,133} It is important to recognize these, as traumatic or unsuccessful attempts may cause diagnostic ambiguity and lead to unnecessary antibiotic use, hospitalization, and patient discomfort. Steps may be taken to minimize patient discomfort and maximize the chance of a successful LP in the setting of a high likelihood of a difficult LP. Have the most experienced EP perform the procedure. Consider the use of US or fluoroscopic guidance. **The EP should never delay administering antibiotics, or other potentially life-saving treatment, because an LP may appear difficult.**

The inability to either visualize or palpate the spinous processes is predictive of a difficult LP in the adult patient. The inability to visualize the spinous processes is associated with an increased risk of a traumatic LP.¹³³ The use of bedside US can assist in the identification of the spinous processes.

A

B

FIGURE 142-11. US image of the L3-L4 lumbar spine in the longitudinal view. **A.** Midline view. The distal tips of the spinous processes are seen as a series of echogenic convexities (arrows). **B.** Lateral view. IMLD, inter-middle laminar distance, ILS, interlaminar space. (Used with permission from reference 117.)

There are several risk factors in children associated with an unsuccessful or traumatic LP.⁹⁸ These include patient-related factors (e.g., young age and inability to visualize the spinous processes), physician factors (e.g., less experience performing an LP), and procedural factors (e.g., no local anesthetic use, patient movement, and advancement of the spinal needle with the stylet in place).⁹⁸

FIGURE 142-12. The US transducer is oriented transversely across the lumbar spine. A mark is placed on each side of the US transducer's midpoint.

EPs have traditionally been taught to keep the stylet in place as the spinal needle is advanced into the subarachnoid space. This will avoid the introduction of epidermal cells into the subarachnoid space and the subsequent development of an epidermoid spinal canal tumor. The stylet-out technique has not been linked to this complication as long as the stylet is used as the needle penetrates the skin.⁹⁸ The greatest benefit of stylet removal appears to occur in young infants when the EP is less likely to feel the spinal needle penetrate the dura. The stylet-out technique allows for continuous monitoring of penetration into the subarachnoid space by direct visualization for CSF return.

AFTERCARE

Clean the excess povidone iodine or chlorhexidine from the patient's back and apply a dressing or bandage to the puncture site. Recumbent positioning will decrease the postural headache that sometimes follows LP, but it has not been shown to decrease the incidence of postdural puncture headache (PDPH).¹³⁴

FIGURE 142-13. The US transducer is oriented longitudinally along lumbar spine. A mark is placed on each side of the US transducer's midpoint.

FIGURE 142-14. Two pairs of marks are obtained. Their intersection (purple dot) marks the spot for the spinal needle entry.

COMPLICATIONS

The use of proper technique is essential when performing an LP. It is important for the EP to be aware of potential complications, know how to recognize them, and know how to manage them. Refer to the article by Evans for a complete review of LP complications.¹³⁵ The most common complication is PDPH whereas the most life-threatening is cerebral herniation. Localized cellulitis, dural abscesses, discitis, and localized bleeding are also potential complications.

CEREBRAL HERNIATION

The most serious complication that may result from an LP is brain herniation or coning.³⁸ Theoretically, if a large pressure gradient exists between the cranial and lumbar compartments, herniation across the tentorial incisura or foramen magnum may occur after removal of CSF from the lumbar area. Patients with increased ICP secondary to intracranial mass lesions, cerebral edema, and acute hydrocephalus are at greater risk for cerebral herniation or coning. Herniation has also been known to occur in patients with meningitis. The role of LP in precipitating brain herniation has been the subject of debate. Several studies suggest that an LP is relatively safe in the patient with increased ICP.¹³⁶⁻¹³⁸ The elevated ICP in IIH is uniform throughout the CNS, so there is no pressure gradient to result in brain herniation. Each individual patient's risks and benefits must be considered before proceeding.

There are case reports of herniation occurring after an LP in patients with meningitis and SAH.¹³⁹⁻¹⁴¹ The actual role that an LP has in precipitating or facilitating the process of herniation is not known.¹³⁹ **Patients with decorticate or decerebrate posture, focal neurologic signs, or no response to pain should receive antibiotics but not an LP.**^{139,141} **This is true even when the CT appears normal in cases of suspected meningitis.**^{139,141} **Obtain a CT scan before performing an LP if there is a suspicion for an SAH.**^{142,143}

POSTDURAL PUNCTURE HEADACHE

The PDPH is the most common complication of an LP.^{144,145} It is thought to be the result of continued CSF leakage at the puncture site. The reason why this causes a headache remains unclear.¹⁴⁶ It is hypothesized that the lower CSF pressure induced by the leakage causes the brain to "sag." This leads to traction on pain-sensitive structures in the brain such as the dura, nerves, and bridging veins.

Intracranial venous dilation and increased brain volume may lead to a neurohumoral response identified as pain.

The headache begins within 24 hours of the procedure in 65% of cases and within 48 hours in 90% of cases.¹⁴⁷ Delayed development of a PDPH 5 to 14 days after the procedure has been reported. The headache typically resolves within 7 days. It has been reported to last several months in rare individuals. The headache is usually located in the frontal or occipital area. It may vary in intensity. The PDPH is usually described as bilateral pressure that is throbbing or achy and improves with supine positioning. Associated symptoms may include nausea, vomiting, neck stiffness, auditory symptoms, and vestibular symptoms.¹⁴⁷

The incidence of PDPH has been reported to be anywhere from 1% to 70%. The wide range is most likely due to the fact there are several identifiable risk factors that influence its development. Age and gender play a significant role.¹⁴⁷⁻¹⁴⁹ The highest incidence occurs in 18 to 30 year olds. There seems to be a decreased incidence after the age of 60, the reason for which is unknown.

The type of needle and its diameter also influence the development of a PDPH.⁵⁹⁻⁶³ This is based upon the amount of trauma and the size of the hole it makes in the dura. Smaller diameter needles and atraumatic needles lower the incidence of PDPH. However, a 22 or larger gauge needle must be used to determine the opening pressure and to collect samples in a timely fashion when performing a diagnostic LP.^{150,151} The bevel orientation should be parallel to the longitudinal dural fibers when using a Quincke needle. This significantly reduces the incidence of PDPH.^{95,152-154} The use of an atraumatic needle may also decrease the incidence of PDPH.^{155,156} These needles are designed to separate rather than shear the dural fibers. Replacement of the stylet before removing the spinal needle has been shown to decrease the incidence of PDPH.¹⁵⁷ Repeated dural punctures have been associated with an increase in the incidence of PDPH.¹⁵⁸

Other nonproven risk factors for a PDPH include psychogenic factors, the rapidity of CSF withdrawal, race, patient positioning, and hydration status. Bed rest for 24 hours was often widely recommended. It has not been shown to decrease the incidence of PDPH.¹⁵⁹⁻¹⁶² Other studies have shown bed rest to increase the risk of PDPH.^{163,164} Early ambulation does not increase the incidence of PDPH.¹⁶⁵ Dehydration was once felt to impair the patient's ability to produce CSF to compensate for the leaking CSF. The incidence of PDPH was independent of daily fluid intake.¹⁶⁶ They postulated that it is the closure of the dural defect and not the CSF loss that is the critical factor in the termination of the PDPH.

Many treatments have been tried to relieve a PDPH. Supine positioning can provide some symptomatic relief for initial or mild PDPHs. A single 300 mg dose of oral caffeine may provide transient relief.^{167,168} Administer 500 mg of intravenous caffeine for more severe headaches.¹⁶⁹ Intravenous caffeine administration resulted in an approximately 70% success rate in treating PDPH.¹⁷⁰ Intravenous caffeine administered prophylactically may minimize the incidence of PDPH.¹⁷¹ There is some promise in the use of triptans.^{172,173} The use of cosyntropin, an ACTH analog, has shown promise in the treatment of PDPH.^{174,175} An occipital nerve block may resolve a PDPH.^{176,177} The pain of a PDPH can be ceased with the administration of gabapentin, hydrocortisone, and theophylline.¹⁶⁸ A greater occipital nerve block can decrease the pain of a PDPH and prevent the more invasive blood patch or transnasal sphenopalatine block.¹⁷⁸ The epidural pumping of normal saline has shown some promise.¹⁴⁵ Transnasal sphenopalatine ganglion block can alleviate the pain.^{179,180}

A more definitive but invasive treatment for the PDPH is the epidural blood patch (Chapter 143).¹⁸¹⁻¹⁸³ This procedure is typically performed by an Anesthesiologist. It involves injecting 10 to 20 mL of autologous blood into the epidural space at the level of the

previous LP. The blood acts to tamponade any further CSF leakage and allows healing of the dural opening. Epidural blood patching is successful in 85% of patients after one injection and about 98% of patients if a second blood patch is required.^{120-122,184-186} Epidural blood patching should be performed no sooner than 24 hours after the LP. Complications of the blood patch include back pain, paresthesias, radiculopathies, and weakness, all of which are transient. A rare complication is the spinal subdural hematoma.¹⁸⁷ Other modalities for PDPH relief that have been used but not widely studied are epidural saline injections, dextrose injections, gelatin injections, and epidural morphine.

INFECTIONS

Local infections including cellulitis, abscesses (e.g., lumbar epidural or spinal cord), and discitis can result from an LP. Performing an LP through an area with a local infection (i.e., a cellulitis or an abscess) can introduce bacteria into the CSF and lead to meningitis. Contamination of the needle by airborne pathogens can also occur. **Always wear a sterile gown and gloves, a mask, and a cap while performing an LP.**^{83,188,189} It is possible for the EP's oral flora to contaminate the field and equipment, resulting in an iatrogenic meningitis.⁸³⁻⁸⁵

It was once thought that an LP could induce meningitis in a bacteremic patient. Further studies have shown this idea to be unfounded.¹⁹⁰⁻¹⁹² **Bacteremia is not a contraindication to performing an LP.** Proper cleaning and disinfecting of the skin, avoiding infected areas with the spinal needle, and using sterile technique will minimize but not eliminate any risk of infection.

HEMORRHAGE

A traumatic LP is a common occurrence and can occur in up to 30% of LPs.¹⁹³ Up to 72% of LPs have anywhere from 1 to over 50 red blood cells.¹⁹⁴ This is a common and usually uncomplicated occurrence in patients with a normal coagulation profile. Traumatic LPs can result in a spinal epidural or spinal subdural hematoma in patients regardless of coagulation abnormalities.¹⁹⁵⁻²⁰⁰ Epidural hematomas most likely result from needle trauma to the internal vertebral plexus or radicular vessels (**Figure 142-15**).¹⁹⁴

FIGURE 142-15. Illustration of the spinal cord and the potential sources of spinal needle-induced bleeding. The correct path of the spinal needle usually avoids the internal vertebral venous plexus.

The radicular vessels course down the length of each nerve root. It has been suggested that the bevel of the spinal needle can induce trauma and bleeding to these vessels much like they produce paresthesias when touching the nerve roots. Spinal epidural hematomas, if large enough, can result in a cauda equina syndrome.²⁰¹

Subdural hematoma or SAH is a rare but catastrophic complication in patients with or without a coagulopathy.¹⁹⁹ One author recommended that the procedure be performed only if necessary in patients with a thrombocytopenia.²⁰² Platelets should be transfused prior to an LP in patients with platelet counts less than 20,000 or if platelet counts are dropping rapidly. The most skilled EP should perform the LP using a 22 gauge or smaller needle.²⁰² The patient should be observed after the LP for the development of neurologic signs suggesting a hematoma (e.g., lower extremity weakness, sensory deficits, or incontinence).

A rare bleeding complication is an intracranial subdural hematoma.^{203,204} This may result from the same mechanism causing a PDPH, namely the downward displacement of the brain from decreased CSF volume and persistent leakage after an LP. This may occasionally cause tearing of the bridging veins and lead to a unilateral or bilateral subdural hematoma. Suspect this diagnosis when a headache sounding like a PDPH lasts for more than a week, is no longer postural in nature, or returns after initially improving.²⁰⁵

MISCELLANEOUS COMPLICATIONS

Neuropathies involving cranial nerves III, IV, V, VI, VII, and VIII have been reported. They most likely result from traction on the nerves caused by low ICP after the LP. Typical complaints may include visual and auditory symptoms. Epidural fluid collections of CSF after an LP can be significant.²⁰⁶ They usually resolve spontaneously with time but can compromise the thecal sac if large enough.

Mild low back pain is a common complaint that results from the local trauma of the needle tract. Transient dysesthesias are common and result from spinal needle contact with the nerve roots. A spinal needle that passes beyond the subarachnoid space into the annulus fibrosis can cause disc herniation. This can result in a discitis and vertebral collapse.²⁰⁷

Intraspinal epidermoid tumors are composed of well-differentiated stratified squamous epithelium surrounding a mass of caseous substance formed by the desquamation of epidermal tissue. They are often congenital but may result from the introduction of epidermal fragments into the spinal canal. This may occur if the stylet of the needle is not used. Spinal epidermoid tumors may present months to years after an LP.²⁰⁸⁻²¹¹

A dry tap is often the result of lateral displacement of the spinal needle. Maintain the spinal needle in the midline while it is being advanced. Not penetrating deep enough with the spinal needle can result in a dry tap. This is especially true in obese patients who may require long (i.e., 7 to 10 inch) spinal needles to gain access to the subarachnoid space. It has been suggested that the standard 3.5 inch spinal needle is adequate for 97% of patients.²¹²

Mechanical complications with the equipment do occur. The spinal needle can break.²¹³ A bent stylet cannot be pulled out of the spinal needle.⁸⁶ Check the equipment before using it.

Prevent secondary injury by always inserting the stylet into the spinal needle before removing it.⁹⁹ Withdrawing the spinal needle without the stylet can result in the aspiration of a lumbar nerve root or arachnoid tissue into the epidural space. The patient may require a laminectomy if this occurs to replace the nerve root or arachnoid tissue. The reinsertion of the stylet will also decrease the incidence of post-LP symptoms (i.e., dizziness, headache, nausea, and tinnitus).⁹⁹

The ICP can be falsely elevated. **Positioning the patient is important when measuring the opening pressure.** Place the patient in the lateral decubitus position and ensure that they relax during the procedure. Do not flex or extend the patient's neck, hip, or knee. Try not to have the patient Valsalva during the procedure. Carefully instruct the patient from the fetal position for needle placement to the lateral decubitus position to measure opening pressure.

It is now common for adolescents and adults to have tattoos on their lower back. It is recommended to perform an LP in an area void of tattoo ink, at a higher or lower interspace, or nicking the skin with a needle or scalpel prior to inserting the spinal needle.^{214,215} All these techniques avoid the spinal needle penetrating through the tattoo ink. The tattoo ink may contain substances that can be irritating or toxic if introduced into the spinal canal.

CSF INTERPRETATION

Proper interpretation of the CSF is an important skill for the EP who performs the LP. **Tables 142-1 and 142-2** list the normal CSF values and the CSF values in a variety of different medical conditions.^{216,217}

CSF PRESSURE

Normal CSF pressure ranges from 70 to 180 mmH₂O in adults and from 50 to 80 mmH₂O in infants and children. Note that many manometer kits use cmH₂O on the demarcations, whereas results are commonly interpreted in mmH₂O. Elevated CSF pressure may be seen in bacterial meningitis, viral meningitis, brain abscesses, tuberculous meningitis, fungal meningitis, encephalitis, meningeal carcinomatosis, SAH, pseudotumor cerebri, and Guillain-Barré syndrome. It may be falsely elevated when the patient is tense or creating a lot of intraabdominal pressure by flexing their knees into the abdomen. The pressure will also be falsely elevated if the patient is in a seated position. Although CSF pressure is not routinely recorded in infants and children (most likely because they are often crying, struggling, or difficult to hold), it should be recorded whenever possible. Low CSF pressure may be the result of a spinal root obstructing the flow of CSF into the needle or obstruction of flow from a spinal mass.

TABLE 142-1 Normal CSF Values

	Preterm infant	Term infant	Child	Adult
White blood cell count (WBC/mm ³)	9 (range 0–32) 57% PMNs	8 (range 0–22) 61% PMNs	0–7 0% PMNs	0–5 0% PMNs
Glucose (mg/dL)	24–63 (mean 50)	34–119 (mean 52)	40–80	50–80
CSF/blood glucose ratio				
Normal ratio	55–105%	44–128%	50%	60–70%
Abnormal ratio	< 0.5–0.6	< 0.5–0.6	< 0.4–0.5	< 0.4–0.5
Protein (mg/dL)	65–150 (mean 115)	20–170 (mean 90)	5–40	15–45

TABLE 142-2 CSF Values in Various Neurologic Conditions

Condition	Appearance	Pressure	Cell count (mm ³)	Glucose (mg/dL)	Protein (mg/dL)
Bacterial meningitis	Clear, cloudy, or purulent	Elevated	500–10,000 + cells with 90–95% PMNs	0–40	> 50
Partially treated bacterial meningitis	Possibly cloudy	Normal or elevated	1–500 cells, lymphs or monos may predominate	Low or normal	> 50 and < 500
Brain abscess	Clear, cloudy, or purulent	Elevated	Possibly > 100,000 cells if abscess ruptures. PMNs predominate.	Normal	< 200
Tuberculous meningitis	Clear, opalescent, or ground glass	Elevated	25–500 WBCs, PMNs early but usually lymphs predominate	10–40	50–500
Fungal meningitis	Clear or cloudy	Elevated	10–500 WBCs, lymphs predominate. PMNs early.	< 40	< 600
Viral meningitis or encephalitis	Clear, may have faint opalescence	Normal or elevated	6–1000 cells, predominance of lymphs. PMNs early.	Normal but may be low with herpes or mumps	< 200
Acute syphilitic meningitis	Clear or turbid	Elevated	100–500 WBCs, usually lymphs	Normal or decreased	< 200
Meningeal carcinomatosis	Clear or mucinous	Elevated	10–500 WBCs, lymphs predominate	< 40	< 500
Subarachnoid hemorrhage	Bloody, xanthochromia, clear	Elevated	1000–3.5 × 10 ⁶ RBCs	Normal, but can be decreased in 10–15% of cases	Increased
Multiple sclerosis	Clear	Normal	0–20 lymphocytes, > 50 rare	Normal	45–75
Progressive multifocal leukoencephalopathy	Clear	Normal	< 10 monos	Normal	Normal
Guillain-Barré syndrome	Clear or xanthochromic	Normal or elevated	Normal, but 10–200 WBCs, predominantly lymphs	Normal	May be as high as 1000
Pseudotumor cerebri	Clear	Elevated	Normal	Normal	Normal
Subacute sclerosing panencephalitis	Clear	Normal	Usually normal	Normal	Increased; check CSF measles titers and CSF gamma-globulin
Neuro-Behçet's syndrome	Clear	Normal or elevated	Up to 3000 WBCs, PMNs predominate	Normal	Increased

A novel device to measure pressure is the Compass LP (Centurion Medical Products, Williamston, MI). This device is a single patient use and disposable unit that attaches to the spinal needle (**Figure 142-16**). It provides a digital readout of the CSF pressure. Further research is required before this device replaces the standard manometer.

**FIGURE 142-16.** The Compass LP Pressure Monitor. (Photo courtesy of Centurion Medical Products.)

CELL COUNTS AND DIFFERENTIAL

A variable amount of white blood cells (WBCs) may be normally present in the CSF depending upon the age of the patient.²¹⁸ Neonates may have up to 32 WBCs/mm³ with 60% polymorphonuclear leukocytes (PMNs). Infants 4 to 8 weeks of age may have up to 22 WBCs/mm³. Most sources consider anything greater than 8 to 10 WBCs/mm³ to be abnormal.^{219,220} Normal adult CSF should contain no more than 5 WBCs/mm³ with a differential consisting predominately of mononuclear cells or lymphocytes. The presence of more than one PMN should be considered abnormal.

Bacterial meningitis cell counts are usually greater than 500 WBCs/mm³ with a predominance of PMNs; though lymphocytosis can uncommonly occur.^{221,222} The CSF will usually contain less than 1000 WBCs/mm³ in patients with viral meningitis and have a differential of 100% lymphocytes. An early viral meningitis (i.e., 48 hours) will have a predominance of PMNs in the CSF, making it difficult to distinguish it from bacterial meningitis.^{1,223,224} Approximately 90% of patients will show a switch to a mononuclear pleocytosis within 8 to 12 hours on repeat LP.²²⁵

Normal cell counts and differentials do not always exclude meningitis. Approximately 95% of the population does not normally have any PMNs in their CSF. The presence of one PMN could represent an abnormality. One PMN may be seen in approximately 5% of normal children. Bonadio reviewed 424 LPs of which 106 had PMNs but no pleocytosis.²²⁶ All 106 patients had negative Gram's stains and cultures. The authors concluded that the older child without pleocytosis or abnormal CSF chemistries can be considered at very low risk for meningitis. Neither the presence of bands nor the quantity of bands was a predictor of bacterial meningitis.²²⁷ Close clinical observation and hospitalization for treatment and repeat LP should be considered until CSF culture results are negative if meningitis is suspected and the CSF is normal or has PMNs.

A traumatic LP can often make the interpretation of the CSF difficult as peripheral WBCs can be introduced into the CSF. Clearing of the red hue of the CSF from the first to last tube suggests that the tap was traumatic. This is not always a reliable sign. The ratio of the RBCs to the WBCs in the blood is compared to the ratio in the CSF. This is based on the assumption that blood introduced into the CSF keeps the ratio of RBCs to WBCs the same. Some use a set RBC to WBC ratio of 1000:1, 750:1, or 500:1.²²⁸ This is not always accurate as a peripheral leukocytosis may often be present. By comparing the ratios, a predicted WBC count for the CSF can be obtained (predicted CSF WBC = CSF RBC \times blood WBC \div blood RBC). The actual WBC count will then be the predicted WBC subtracted from the observed or measured WBC (actual CSF WBC = observed CSF WBC – predicted CSF WBC).

Most studies on patients with traumatic taps that did not have meningitis have shown that these formulae are often inaccurate.²²⁹ The observed CSF WBC count is often less than the predicted CSF WBC count.²³⁰ This raises concerns that the diagnosis can be missed in the presence of meningitis. The use of the formula in patients who had meningitis found many false-positive and false-negative results.²³¹ They investigated the value of an O:P ratio (observed CSF WBC/predicted CSF WBC) in predicting the presence of meningitis. They found that a ratio greater than 10 had a sensitivity of 88% and a specificity of 90% in predicting culture-positive meningitis. **They concluded, along with others, that pleocytosis in bacterial meningitis is rarely masked by a traumatic tap.**^{231,232} The O:P ratio of ≤ 0.01 can be used to identify patients with traumatic LPs who do not have meningitis.²³³

GLUCOSE

Normal values for CSF glucose are listed in **Table 142-1**. Compare the ratio of CSF glucose to a simultaneously determined blood glucose level to determine if low CSF glucose (hypoglycorrhachia) exists.²²⁴ The ratio is abnormal in preterm infants if it is lower than 0.5 to 0.6.²³⁵ A ratio of less than 0.4 to 0.5 in children and adults is abnormal. Approximately 58% of patients with bacterial meningitis will have a glucose of < 40 mg/dL. The sensitivity for detecting bacterial meningitis increases to about 70% if a CSF-to-serum glucose ratio of < 0.31 is used.²³⁶ The normal steady state of 0.6 tends to decrease as serum glucose increases. Ratios of less than 0.3 should be considered abnormal in cases of severe hyperglycemia. The CSF-to-serum glucose ratio is less accurate when there are rapid changes in the serum glucose. **A low CSF-to-serum glucose ratio should always raise the concern of bacterial or fungal meningitis.** Other conditions such as tuberculous or syphilitic meningitis, meningeal carcinomatosis, or SAH can be the etiology. Approximately 15% to 20% of patients with an SAH will have hypoglycorrhachia.^{237,238} Normal CSF-to-serum glucose ratios are usually seen with aseptic meningitis, encephalitis, brain abscesses, and subdural empyemas.

PROTEIN

The normal CSF protein levels are listed in **Table 142-1**. Elevated CSF protein levels, often greater than 150 mg/dL, are seen in acute bacterial meningitis. Other causes of increased CSF protein include any type of meningitis, encephalitis, CNS tumors, SAH, demyelinating syndromes, and a traumatic LP.²³⁹ Correct the CSF protein by subtracting 1.1 mg/dL of protein for each 1000 RBCs in traumatic LPs.²⁴⁰

GRAM'S STAIN

The Gram's stain is a very reliable test when performed by properly trained individuals. It is positive in identifying approximately

80% of bacterial CNS infections.²⁴¹ The probability of detecting bacteria on a Gram's stain depends upon the number of bacteria present in the CSF.²⁴² Approximately 25% of smears are positive with $\leq 10^3$ colony-forming units (CFU)/mL, 60% with 10^3 to 10^5 CFU/mL, and 97% with $> 10^5$ CFU/mL. False negatives can result from partially treated meningitis where the sensitivity decreases to about 60%.²⁴³ False positives can result from the use of contaminated LP trays, contaminated reagents, or the use of an unoccluded spinal needle.²⁴⁴

CSF CULTURES

Obtain CSF cultures in all patients suspected of having meningitis.⁴ Positive cultures are assumed to be 100% specific but may only occur in 80% of patients thought to have bacterial meningitis.²¹⁸ Transport the CSF specimens to the laboratory promptly, as *H. influenzae* and meningococcus will not survive storage or variations in temperature. A small number of patients treated for meningitis with antibiotics have a final diagnosis of bacterial meningitis.^{245,246} The decreased prevalence of bacterial meningitis is due to vaccination.^{245,246} Antibiotics administered prior to LP can sterilize the CSF. There is probably a window of about 2 to 3 hours where antibiotics do not affect the culture results.²⁴⁷ This depends upon the amount of bacteria in the CSF and the elapsed time from initiation of antibiotics. The percentage of positive CSF cultures decreases from 33% to 4% and Gram's stains from 41% to 7% when antibiotics are given prior to LP.²⁴⁸ The effect of full intravenous antibiotic treatment on CSF cultures was studied by performing an initial LP and then a repeat LP in 44 to 66 hours.²⁴⁹ All but one of the cultures became negative, whereas the cytology and biochemistry were not affected. They concluded that partial treatment with antibiotics may alter the culture results but does not distort the other characteristics of a "bacterial" CSF.

SUBARACHNOID HEMORRHAGE

It is imperative to interpret the CSF results correctly when an LP is performed after a negative head CT to rule out the possibility of an SAH.²⁵⁰ Most sources agree that the presence of xanthochromia, which results from lysis of red blood cells, confirms the presence of intracranial bleeding.²⁵¹⁻²⁵³ Xanthochromia by spectrophotometry was found to be only slightly better than visual inspections.²⁵⁴ Xanthochromia, when measured by spectrophotometry, has a sensitivity that approaches 100% when performed between 12 hours and 2 weeks from the initial SAH. Do not accept gross xanthochromia as a positive finding.²⁵⁵⁻²⁵⁷ Gross xanthochromia can be a false-positive result. Always rely on a spectrophotometric determination of xanthochromia.^{258,259} Xanthochromia can develop in specimens within a few hours if the tap was traumatic.²⁶⁰ One cannot rely on the finding of xanthochromia if the WBC count is $> 10,000$ or if the analysis of CSF samples is delayed.²⁶⁰

So how should patients who present within 12 hours of their symptom onset be managed? Delaying an LP for 12 hours would require holding patients in the ED or admitting everyone who required an LP for evaluation. This presents a legitimate logistical problem. Edlow and Caplan suggest that patients that have a negative CT should undergo immediate LP.²⁶¹ If the CSF is persistently bloody without xanthochromia and clinical suspicion is high, vascular imaging should be the next step.²⁰

FUTURE CONSIDERATIONS

The Injeq System (Injeq Oy, Tampere, Finland) may make LPs easier. The system consists of the specialized spinal needle, the cable, and the monitor (**Figure 142-17**).²⁶² The needles come in a variety of sizes. The needle has an electrode at the tip of the stylette that senses the

FIGURE 142-17. The Injeq System. **A.** The IQ spinal needles. **B.** The sensor on the stylette tip inside the spinal needle. **C.** The spinal needle attached to its cable and monitoring unit. (Photos courtesy of Injeq Oy.)

environment of the needle tip. The sensor uses bioimpedance analysis to differentiate tissue types. The sensor measurement is different for CSF versus other tissues. The company is hoping to get U.S. FDA approval in 2018.

SUMMARY

Most LPs will be performed in suspected cases of meningitis or SAH after a negative head CT. The risks of performing an LP need to be weighed against the potential benefits of diagnosing these two potentially life-threatening illnesses promptly. Knowledge of the proper indications, contraindications, technique, and interpretation of the CSF findings will undoubtedly help the EP to minimize the complications that can be associated with the procedure. Although most complications are rare, awareness of their existence, presentation, and proper treatment is imperative.

Blood Patching for Postdural Puncture (Lumbar Puncture) Headache

Gunar Subieta, Maria Torres, and Ned Nasr

INTRODUCTION

The epidural blood patch (EBP) has been used for the effective relief of postdural puncture headache (PDPH) for well over 50 years.¹ It continues to be the gold standard for therapy of this debilitating condition.²⁻⁴ The advent of spinal and epidural anesthesia during the early twentieth century required techniques for treating PDPH. The risk of PDPH was recognized from a dural puncture. Gormley was

TABLE 143-1 The International Headache Society Criteria for PDPH⁷

Dural puncture was performed
Headache associated with at least one of the following:
Hyperacusis
Nausea
Neck stiffness
Photophobia
Tinnitus
Headache develops within 5 days of dural puncture
Headache improves within 15 minutes after lying
Headache resolves either:
Spontaneously within 1 week
Within 48 hours of EBP
Headache worsens within 15 minutes after sitting or standing

the first to describe EBP as a therapy for PDPH in 1960.⁵ EBP was not widely used until nearly a decade later.⁶

The International Headache Society classifies the PDPH as an instance in which the criteria for low cerebrospinal fluid (CSF) pressure is met without any other possible explanation (**Table 143-1**).⁷ It can and does occur after a lumbar puncture.⁸ The patient presents with a bilateral positional headache aggravated by sitting or standing. The headache is better or relieved by the recumbent position. It is associated with at least one typical symptom (e.g., nausea) and an atypical symptom (e.g., visual and/or auditory disturbances). The onset can occur at any time within 5 days of any procedure involving the puncture of the dural membrane (i.e., PDPH).

A spontaneous intrathecal CSF leak is uncommon. It occurs in 0.05% of the population. A spontaneous leak is usually associated with congenital structural abnormalities or connective tissue diseases (e.g., Marfan's syndrome or Ehlers-Danlos syndrome).

A breach of the dural membrane may be intentional or accidental depending on the circumstances. The highest frequency of accidental punctures occurs in young females during the perioperative delivery period in conjunction with an epidural placement. Ruptures associated with diagnostic procedures may present with headache and are usually seen in pediatric or geriatric patients.⁹

ANATOMY AND PATHOPHYSIOLOGY

The dural sac creates a fluid-filled space that surrounds the brain, is continuous throughout the spine, and ends at the level of the midsacrum. This space contains approximately 150 mL of CSF. The CSF is constantly secreted and recycled by reabsorption. More detailed information regarding the CSF can be found in Chapter 142.

PDPH development is still a subject of discussion in terms of its etiology.¹⁰ There are many theories for the PDPH. One theory is the loss of CSF at a higher rate than it is produced.¹¹ This results in a reflex vasodilation and an increased cerebral blood flow to fill the gap left by this loss and venous congestion.¹¹ The body responds by trying to maintain a constant intracerebral volume. This theory may explain why vasoconstrictors such as caffeine and theophylline have a role in the relief of PDPH. The EBP is thought to work by forming a clot over the dural tear that is causing the CSF leakage and by increasing intracranial pressure via a mass effect. The EBP relieves tension on cerebral bridging veins and subsequently reduces the cerebral vasodilation. Another theory suggests that the loss of the CSF cushion of the brain results in traction of the meninges, cranial nerves, and cervical structures.¹² It is hypothesized that traction on the nerves is responsible for the symptoms of a PDPH. Traction on the trigeminal nerve causes a frontal headache. Traction on the abducens nerve causes visual symptoms. Traction on the vagus nerve causes nausea. Traction on the cervical nerves may

cause referred pain in the occipital nerve distribution, the neck, and the shoulders. The patient will present with symptoms based on the nerve or nerves under traction.

The type of needle affects the outcome (Chapter 142). Pencil needles are more traumatic to the dura and may result in a higher inflammatory response, decreasing the amount of leakage. The larger the caliber of the needle, the higher is the likelihood of a CSF leak. Many attribute worse symptoms with larger punctures.¹³

The incidence of PDPH has been associated with age between 18 and 30 years, female sex, low body mass index, prior history of headaches, and prior motion sickness.^{4,14} Patients with a prior history of migraines are not at a higher risk than other populations.¹⁵ Obesity is protective and prevents a PDPH.^{16,17}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a PDPH is broad. A PDPH may present with a frontal to occipital headache occurring within 12 hours of a procedure and up to 5 days after (Table 143-1). It is usually accompanied by symptoms of nausea, vomiting, and neck stiffness. Unusual symptoms may include visual and auditory disturbances. These include diplopia, hyperacusis, photophobia, and tinnitus. **Always consider the timing of symptoms.**

The history and physical examination are paramount. They must be comprehensive since the differential diagnosis includes the possibility of an abscess, hematoma, hypertensive emergency, pneumocephalus, postpartum cerebral angiopathy, preeclampsia, progression of an intracranial lesion, subarachnoid hemorrhage, or a thrombosis.^{18,19} Low back pain makes the differential diagnosis include arachnoiditis, aseptic meningitis, myofascial pain, neurologic symptoms from local anesthetics, or septic meningitis.²⁰ The presenting patient without associated symptoms raises the possibility of primary headaches (e.g., classic migraine, common migraine, or tension headache) or secondary headaches (e.g., cervicogenic headache, giant cell arteritis, or medication overuse headache).²¹ **Always be cognizant of red flags such as altered mental status, scalp tenderness, fever, history of cancer, neurologic deficits, and recent travel.** Obtain a complete lab work and imaging studies as warranted.²²

Approximately 70% of PDPHs spontaneously resolve within 2 weeks. Some PDPHs may take up to months or years to resolve.^{23,24} Surgical intervention may be required to relieve the PDPH in a minority of patients.²⁵

INDICATIONS

Anesthesiologists and Pain Management Physicians recommend aggressive hydration, caffeine supplementation, analgesia with nonsteroidal anti-inflammatory drugs (NSAIDs), and opiates as first-line treatments.^{2,3,8,26-28} These have been proven to be partly efficacious in multiple randomized controlled studies.²⁹ Additional interventional therapies include peripheral nerve blocks at the level of the sphenopalatine ganglion and the occipital nerve.^{28,30,31} Their mechanisms are not well understood. Promising medical management strategies include cosyntropin (i.e., synthetic adrenocorticotrophic hormone) with the belief that this hormone will increase CSF production.^{28,32,33} Receptor agonists (e.g., sumatriptan) have been used with mixed results.^{28,34,35}

The autologous EBP has become the standard of care for the management of persistent symptoms.^{3,36,37} It was first described in 1960 to improve PDPH symptoms.⁵ Multiple studies have demonstrated that the volume ideally is 15 to 20 mL.³⁸ The mechanism of action is thought to be due to immediate compression of the space causing

cephalic displacement of the fluid, delayed clot formation at the level of the puncture site, and fibroblastic activity at the level of the puncture site.³⁹ It has been shown to be effective if performed sooner for the treatment of a PDPH. The EBP may reduce the patient's length of stay and improve satisfaction. A Cochrane review performed in 2010 does not advocate for a prophylactic EBP on every dural puncture.⁴⁰

CONTRAINDICATIONS

The presence of an active infection at the site of epidural needle placement, bacteremia, presumed meningitis, and sepsis are absolute contraindications to performing an EBP.⁴¹ The headache pain in these cases may have an etiology other than the PDPH. Discuss treatment with an EBP with patients with cancer or immunodeficiency syndromes and their Oncologist or Primary Care Provider before proceeding.

EQUIPMENT

- Angiocatheter, 20 gauge or larger
- Chlorhexidine or povidone iodine swabs
- Tuohy needle, usually 18 gauge
- Needles, various sizes
- 1% lidocaine
- 0.9% saline
- Syringes, 5 and 10 mL
- 5 mL glass or plastic syringe for loss of resistance (LOR)
- 10 mL ampule of 0.9% sterile saline to be used in syringe for LOR
- Sterile adhesive drape
- Sterile gauze 4×4s
- Surgical cap for the patient and providers
- Surgical masks and sterile gloves
- Butterfly needle(s) for blood draw and tourniquet
- Fluoroscopic unit, optional

The Touhy needle was designed to enter through the dura with minimal trauma. The Touhy needle comes in epidural kits and separately (Figure 143-1A). The tip is curved (Figure 143-1B). The shaft has markings every 1 cm (Figure 143-1A). The stylet fits within the Touhy needle and functions to close off the inside (Figure 143-1C).

The sterile epidural catheter kit contains all the required equipment (Figure 143-2). This includes the local anesthetic, skin antiseptic, and drapes. It is wise to have additional 5 and 10 mL sterile syringes.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Positioning is a crucial step in successfully accessing the epidural space. Place the patient in a sitting position on the level gurney with their arms and shoulders relaxed (Figure 143-3). The legs may be crossed or extended with both legs in the same position; ensure the patient is comfortable. Ensure the patient's spine is perpendicular to the floor. Minimize the distance from the edge of the

FIGURE 143-2. An example of a prepackaged commercial epidural kit.

A

B

C

FIGURE 143-1. The Touhy needle. **A.** The needle. **B.** Two views of the needle tip. **C.** The stylet in the needle.

bed to the patient's back. Ask the patient to push their lower back toward the edge of the bed while tucking their head into their chest to assist in proper positioning. The EBP may be attempted with the patient lying in the lateral position, but identification of the appropriate structures may be more challenging.

Carefully inspect the prior puncture site and surrounding tissues. The prior puncture site can be determined in most cases. **The appropriate location for needle insertion should be at the same level.** Confirm the insertion site of the needle by gentle palpation of the posterior iliac crests and the corresponding interspinous space at the same level. This is usually L3-L4. Bruising and tenderness to palpation at the previous puncture level are common. **Any erythema, purulence, and signs of infection are absolute contraindications to proceeding with an EBP.**

FIGURE 143-3. Positioning of the patient.

Don a cap, face mask, sterile gown, and sterile gloves. Have the patient apply a cap and a mask. Move the patient's hair under the cap and out of the way. Have an assistant wipe, clean the skin of the patient's back to remove any debris, dirt, and dried blood. Apply the chlorhexidine or povidone iodine to the area and allow it to dry.

TECHNIQUE

Apply sterile drapes to demark a sterile field. Anesthetize the skin at the puncture site with 1% lidocaine. Insert the Touhy needle with its introducing stylet. Advance the Touhy needle slowly until the supraspinous ligament is encountered. Firmly hold the position of the Touhy needle so it does not move. Remove the stylet. Attach a sterile syringe with sterile saline to the Touhy needle. Advance the Touhy needle with constant or intermittent pressure on the syringe plunger. The Touhy needle will pierce and pass through the interspinous ligament and then the ligamentum flavum. A loss of resistance will be felt upon passing through the ligamentum flavum from pressure on the syringe plunger. Saline should be able to be injected freely.

A second provider should be obtaining the blood to inject through the Touhy needle for the EBP while the first provider is obtaining access to the epidural space. The hand, forearm, and antecubital fossa are the easiest locations for access. **Strict attention to sterile technique is essential. The second provider should use universal precautions (i.e., a cap, a mask, a sterile gown, sterile gloves) and drapes.** Clean the patient's arm of any dirt and debris. Apply chlorhexidine or povidone iodine and allow it to dry. Apply sterile drapes to demarcate a sterile field. Use a large-bore butterfly needle or a standard angiocatheter. Obtain at least 20 mL of blood divided into 10 mL aliquots in syringes. **Ensure the syringes used to collect the blood remain sterile throughout the process.** The sterile syringes with the patient's blood will be given to the provider obtaining epidural access when ready. **Do not obtain the blood too soon or it may clot in the syringes before it is injected into the patient's back.**

Hand the sterile syringes with the patient's blood to the practitioner who accessed the epidural space. Attach the sterile syringe with the collected blood to the Touhy needle. **Inject the blood into the epidural space slowly and in 5 mL increments (Figure 143-4).** The patient commonly feels increased pressure and tightness at the injection site. There is no set agreed upon amount of blood that needs to be given for relief of a PDPH. The range of 10 to 20 mL is usually sufficient.^{41,42}

FIGURE 143-4. The epidural blood patch.

FIGURE 143-5. Place the fluoroscopy unit so the screen is visible while inserting the Touhy needle.

Remove the Touhy needle after the blood has been injected. Hold pressure to the injection site. Apply a bandage or a small sterile dressing.

FLUOROSCOPY GUIDANCE

The use of fluoroscopy with the EBP procedure can increase the effectiveness when compared to the blind insertion technique.⁴³ Position the fluoroscopy unit so that the monitor can be easily seen (Figure 143-5). Position the foot pedal in a convenient location to be stepped upon to activate the fluoroscopy when required. Position the patient, clean and prep the skin, and anesthetize the puncture area as described above. Insert the needle under fluoroscopy until the tip is in the epidural space (Figure 143-6). Some physicians inject 9 to 10 mL of autologous blood mixed with 1 mL of contrast material (Figure 143-6). This allows visualization of the blood entering the epidural space and ensures that it is being injected into the proper location.⁴³

AFTERCARE

It is recommended for patients to lay flat for at least 2 hours after the EBP with intravenous fluid running at a maintenance rate. Instruct the patient upon discharge not to do any heavy lifting, straining, or strenuous activity. Increase oral fluid intake for at least 24 hours. Arrange appropriate follow-up. The patient should

FIGURE 143-6. Fluoroscopy images. Positioning of the Touhy needle (right). Injection of autologous blood and contrast (left).

return to the Emergency Department immediately if they experience bowel or bladder dysfunction, erythema or tenderness at the injection site, fever, headache with worsening intensity, neck stiffness, numbness or weakness in the lower extremities, progressively worsening photophobia, or worsening nausea and vomiting.

Severe headaches may take up to 24 hours to resolve after an EBP. A second EBP may be necessary in some cases. Over 75% of patients with a PDPH attain complete resolution of symptoms after a single EBP. Over 95% of the remaining patients had complete resolution of symptoms after a second EBP.

COMPLICATIONS

The complications associated with an EBP are similar to those of lumbar puncture (Chapter 142) and epidural catheter placement. There is the additional complication of possibly contaminated blood injected into the epidural or intrathecal space. EBP is commonly avoided in febrile or septic patients as the risks of developing meningitis are quite real. A low-grade fever of a known cause being appropriately treated is not an absolute contraindication for an EBP in the presence of a PDPH. Neurologic complications can be related to compression (e.g., subdural hematoma, cauda equina syndrome, and lumbovertebral syndrome).⁴⁴ These can usually be seen with larger blood volumes injected. Back pain is the most common complication and usually resolves after 48 hours. The back pain can last up to a month in some cases. Other symptoms may include neck pain, lower extremity radicular pain, and temperature elevation. Inflammatory acute arachnoiditis is a rare complication that may be seen within the week following an EBP. The symptoms consist of severe radicular back pain and magnetic resonance imaging diagnosis of adhesions between the lumbar nerve roots.

SUMMARY

An EBP is a consistently reliable means of alleviating a PDPH in patients who have failed conservative management of their symptoms. An EBP is a relatively low-risk procedure when done properly, using sterile technique, and appropriate patient selection. It should be offered to patients presenting with a PDPH. Appropriate diagnosis of a PDPH is essential. An EBP in the setting of meningitis or other neurologic syndromes may be deleterious to the patient.

Burr Holes

Caleb P. Canders, Noah T. Sugerman, and Amir Rouhani

INTRODUCTION

Skulls with burr holes have been found dating back 10,000 years.¹ One of the oldest written records of a burr hole placement was between 2000 and 1700 BC.² The ancient history of burr holes is well described.¹⁻⁴ A surgical algorithm included the placement of burr holes in the Continental Army.⁴

Patients with a closed head injury and expanding intracranial hematomas require urgent decompression and control of hemorrhage. Burr hole drainage of epidural and subdural hematomas is uncommonly performed in the Emergency Department but can be lifesaving when timely neurosurgical intervention is not possible. **Burr hole drainage is indicated in patients with suspected increased intracranial pressure and evidence of tentorial herniation or upper brainstem dysfunction.**⁵ There has been less need to make exploratory burr holes in head-injured patients since computed tomography (CT) scanning is widely available.

Burr holes can be lifesaving on rare occasions when the patient is worsening neurologically or has blown a pupil and CT scan is unavailable. Suspect a space-occupying lesion when there is clinical evidence of tentorial herniation or upper brainstem dysfunction. This includes progressive deterioration in the patient's level of consciousness, a fixed and dilated pupil, hemiparesis, posturing (i.e., decerebrate or decorticate), or flaccidity.

The placement of a temporal burr hole on the side of the fixed and dilated pupil to decompress an epidural or subdural hematoma can be lifesaving.⁶ Up to 70% of patients with evidence of brainstem dysfunction soon after head trauma have significant intracranial mass lesions, most of which are extra-axial blood collections.⁷ With adequate training, burr hole drainage of acute intracranial hematomas can be successfully performed in the Emergency Department by Emergency Physicians.⁸⁻¹²

ANATOMY AND PATHOPHYSIOLOGY

A significant proportion of patients with fatal head injuries die before reaching the hospital. Death is usually secondary to an expanding intracranial hemorrhage, basilar skull fractures with associated injury to the venous sinuses, intracranial carotid artery lacerations, or major cortical blood vessel lacerations. Skull fractures are present in up to 90% of adults who develop a traumatic intracranial hematoma. Children are less likely to suffer a skull fracture after head trauma than adults due to the relative plasticity and malleability of their skulls.

Injury to the middle meningeal artery, or its branches, is a frequent cause of severe intracranial hemorrhage following head trauma. This artery is a branch of the maxillary artery and enters the cranium via the foramen spinosum. It is usually located between the periosteal and meningeal layers of the dura mater. It divides into anterior and posterior branches after entering the skull. The larger branches of the middle meningeal artery lie within the dura and are accompanied by veins. Their superficial location in the dura produces grooves on the interior of the cranium and makes them vulnerable to injury, especially from temporal bone fractures. The bony vault of the skull is fairly thick, approximately 5 mm in thickness, and shows considerable individual and regional variation. The temporal bone, in particular the squamous temporal bone, is much

FIGURE 144-1. Hematomas requiring drainage through a burr hole. **A.** Illustration of an epidural hematoma. **B.** CT scan of an epidural hematoma. **C.** Illustration of a subdural hematoma. **D.** CT scan of a subdural hematoma.

thinner than other areas of the skull. This makes it more vulnerable to a fracture with an associated injury to the underlying middle meningeal vessels.

Posttraumatic epidural hematomas usually develop in the temporal or temporoparietal location as a result of an injury to the middle meningeal vessels (**Figures 144-1A and 144-1B**). More than half of all epidural hematomas result from an injury to the middle meningeal artery. Epidural hematomas occur laterally over the cerebral hemispheres with the epicenter at the pterion in approximately 70% of patients (**Figure 144-2**). The remaining epidural hematomas are

distributed in the frontal area, occipitoparietal area, and the posterior fossa. Other sources of epidural hematomas include a torn venous sinus or an injury to the carotid artery before it enters the intracranial dural mater.

Subdural hematomas are collections of blood between the dura mater and the brain (**Figures 144-1C and 144-1D**). They usually result from tearing of a bridging vein as the brain moves within the skull during blunt head trauma.⁷ The patient will present with an abnormal neurologic examination minutes to hours after the acute injury.

FIGURE 144-2. Percentages of epidural hematomas by anatomic location.

Pupillary changes are not an early sign of an intracranial hematoma but rather a sign of transtentorial (i.e., uncal) herniation causing compression of the oculomotor nerve. Other causes of acute pupillary changes need to be ruled out. Hematomas are found ipsilateral to the pupillary change in 85% of cases.

INDICATIONS

There are a few indications to emergently place a burr hole in the Emergency Department. These include the emergent drainage of an intracranial hematoma in a patient with a reduced Glasgow Coma Score (GCS) of < 8 with a fixed and dilated pupil, monitoring of intracranial pressure, and the emergent cannulation of the ventricular system (Chapter 147). This procedure may be performed by trained Emergency Physicians if a Neurosurgeon has been consulted and is not immediately available. Consider a burr hole if a Neurosurgeon is not available and the signs of brain herniation are present before transferring the patient.^{13,14}

CONTRAINDICATIONS

The only absolute contraindication to burr hole placement is a patient who is coagulopathic. Otherwise, the available Emergency Physician with the most skill and experience in performing this technique should be the one to place the burr hole. Relative contraindications include localized infections of the scalp and patients who are thrombocytopenic. This procedure should not be performed by those unfamiliar with the technique and its complications. Performing it is controversial if it delays transfer of the patient to a center with neurosurgical services if the patient has signs of brain herniation.^{13,14}

A coagulopathy or thrombocytopenia makes a burr hole dangerous to perform. The use of anticoagulants and antiplatelet agents by the patient increases their risk of hemorrhagic complications. Consider reversing these conditions by administering prothrombin complex concentrate (PCC), fresh frozen plasma, or platelets prior to the procedure. A mild elevation in the international normalized ratio (INR) up to 1.6 may be acceptable to place a burr hole.¹⁵

EQUIPMENT

- Sterile prep kit
- Sterile gloves and gown

- Face mask with an eye shield or goggles
- Cap
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- 1% or 2% lidocaine containing epinephrine
- 22 gauge needles
- 5 mL syringe
- #10 scalpel blades
- #11 scalpel blades
- #3 scalpel handle
- Bipolar cautery, optional
- Self-retaining mastoid retractors
- Handheld drill, Hudson brace or air-powered
- Skull perforator bits
- Conical burr bits
- Small hook
- Bone wax
- Thrombin-soaked Gelfoam
- Periosteal elevator
- Suction catheter kit
- Head covers, masks, and sterile gowns
- Ventriculostomy catheter (optional)
- Bone rongeur
- Mayo scissors
- 4-0 nylon suture
- Potts scissors

The required equipment is stored and contained within a prepared sterile tray that can be obtained from the Operating Room or hospital central supply (**Figure 144-3**). A completely disposable, sterile, and single patient use instrument set is also available (Spectrum Surgical Instruments Corp., Stow, OH). The Hudson brace drill is a handheld device consisting of a stabilizer handle in series with a rotating handle (**Figure 144-4**). The distal end has a snap lock chuck that slides to allow easy insertion and removal of the bits. The perforator bits have a sharp point and come in a variety of shapes and sizes (**Figure 144-5**). The tip is designed to penetrate the inner table of the skull and lock without allowing it to puncture the dura or the brain (**Figure 144-6**). **Exercise extreme caution when using**

FIGURE 144-3. The contents of the sterile hospital-prepared burr hole tray.

FIGURE 144-4. The Hudson brace drill.

the perforator bit, as the bit may not lock when it penetrates the inner table of the skull. The burr bits are rounded and used to enlarge the hole made by the perforator bit (**Figure 144-6**).

There have been several modifications of a twist drill for making a burr hole.^{16,17} These modifications are meant for the Operating Room or for use by Neurosurgeons. They are not for general Emergency Department use. These devices are more complicated than using the Hudson brace. Very little information exists on their use in the literature.

FIGURE 144-5. Examples of perforator bits (*left*) and burr bits (*right*).

FIGURE 144-6. The perforator bit is used to make a hole through the skull and just penetrate the inner table of bone (red arrow on the left). The burr bit is used to enlarge the hole (red arrow on the right).

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Obtain a CT scan of the head to determine the presence of an acute subdural or epidural hematoma to determine the location and extent of the hematoma, to rule out the presence of a mass, and to determine if there is herniation. Obtain a complete blood count and a coagulation profile to ensure that the patient is not thrombocytopenic or coagulopathic. These may require reversal with the administration of PCC, fresh frozen plasma, and/or platelets.

Explain the risks, benefits, and complications of the procedure to the patient and/or their representative. Obtain an informed consent if the patient is conscious. However, the patient who is deteriorating neurologically with tentorial herniation usually loses consciousness and time is of the essence. This may limit obtaining an informed consent. Document the circumstances of not getting consent in the medical record.

Determine the site for the skin incision and the burr hole (**Figure 144-7**). The burr hole should be placed over the center of the intracranial hematoma. CT images can assist in determining the location. A frontal or anterior burr hole is typically made just anterior to the coronal suture and 3 cm lateral to the midline, approximately along the midpupillary line (**Figure 144-7A**). The coronal suture is often palpable. If not, draw a perpendicular line midway between the lateral canthus of the orbit and the external auditory meatus. The frontal burr hole can be used to drain an intracranial hematoma or to perform a ventriculostomy. The temporal burr hole is made two finger breadths above the zygomatic arch and two finger breadths anterior to the external auditory meatus (**Figure 144-7B**). The parietal or posterior burr hole is made two finger breadths behind the external auditory meatus and three finger breadths above the mastoid process (**Figure 144-7B**).

Prepare the patient. Orotracheally intubate the patient to protect and secure the airway. Insert a nasogastric tube to decompress the stomach. Shave the scalp at least 5 cm in all directions from the proposed skin incision. **This procedure requires strict aseptic technique.** Clean the skin of any hair remnants from shaving, dirt, or debris. Cleanse the skin first using 70% alcohol followed by povidone iodine or chlorhexidine solution. Allow the povidone

FIGURE 144-7. Typical locations for burr holes. **A.** Superior view of the skull. **B.** Lateral view of the skull.

iodine or chlorhexidine solution to dry. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Isolate the surgical field by using sterile drapes. Prophylactic intravenous antibiotic coverage is recommended if time permits. Administer a broad-spectrum antibiotic that covers gram-positive skin flora. Position the patient so that the proposed incision site is visible and easily accessible. Place the patient supine with a folded blanket or towel under the ipsilateral shoulder. Turn the head to the contralateral side if the cervical spine has been cleared. Instruct an assistant to hold and steady the patient's head.

TECHNIQUES

BURR HOLES

Identify the site to make the burr hole. Infiltrate 5 mL of lidocaine containing epinephrine along the proposed incision site and down to the level of the periosteum on the skull. This will result in analgesia and vasoconstriction that may aid in hemostasis. Make a 2 cm skin incision centered about the site to make the burr hole and straight down to bone. The incision must traverse all layers of the scalp including the skin, subcutaneous tissue, temporalis muscle (if present), and the periosteum. Remove the periosteum overlying the skull by scraping it away with a periosteal elevator. **The periosteum will otherwise get caught in the perforator bit and make it difficult to turn.** Insert a small self-retaining retractor into the incision (**Figure 144-8A**). Hemostasis can often be obtained with the use of the retractor or cautery. Small bleeding vessels may be tied off with absorbable suture (**Figure 144-8A**).

Fit the Hudson brace drill with a perforator bit. Grasp the stabilizing handle of the Hudson brace with the nondominant hand. Grasp the rotating handle with the dominant hand. Place the tip of the perforator bit against the skull (**Figure 144-8B**). Turn the rotating handle clockwise with the dominant hand using a smooth and slow motion. **Always maintain the drill perpendicular to the skull with firm, controlled pressure on the Hudson brace drill.** Frequently remove the perforator bit to examine the hole. Irrigate the area with

normal saline. Use suction to remove the bone fragments and the irrigation fluid. Gently probe the hole to determine if the inner table has been penetrated. Continue to drill until the inner table has been penetrated or the perforator bit locks (**Figure 144-8C**). **Do not apply too much downward pressure on the brace to prevent it from plunging into the brain. Exercise extreme caution as the bit does not always lock when the inner table is perforated.**

Remove the perforator bit from the Hudson brace drill. Place the burr bit on the Hudson brace drill. Place the burr bit into the hole in the skull. Hold the Hudson brace drill as described above. Rotate the handle clockwise to enlarge the hole in the skull (**Figure 144-8D**). Frequently remove the burr bit to examine the hole. Irrigate the area with normal saline. Use suction to remove the bone fragments and the irrigation fluid. Continue to drill until the hole in the inner table is enlarged enough to accept the tip of the bone rongeur. **Do not apply too much downward pressure on the Hudson brace drill to prevent it from plunging into the brain.**

The clot of an epidural hematoma will be obvious as it separates the inner table of the skull from the dura. This clot will be gelatinous in consistency. Drainage through a single burr hole can be difficult. Free the underlying dura from the bone edge with a Penfield elevator. **Gently insert the elevator between the inner table of the skull and the dura. Gently separate the dura from the skull.** Enlarge the burr hole in order to facilitate aspiration of the blood clot. Insert a bone rongeur into the hole. Take small bites of the skull to enlarge the hole (**Figure 144-8E**). **Do not be concerned with making the hole smooth or symmetric.** The Neurosurgeon will later trim and repair the bony defect if and when the patient goes to the Operating Room. Bleeding from the bone can be controlled with bone wax or a local hemostatic (e.g., Gelfoam).

HEMATOMA DRAINAGE

An epidural hematoma is aspirated by gentle suction and irrigation with normal saline through an adequate bone opening (**Figure 144-8E**). **Pay close attention to the temperature of the irrigation solution. It should ideally be body temperature.** Use wall suction with a #9 or #11 French aspirator.

Epidural and subdural hemorrhages are usually clotted in the acute stages. In the event that an epidural hematoma is not identified

FIGURE 144-8. Drainage of an epidural hematoma. **A.** An incision is made through the skin, subcutaneous tissue, temporalis muscle, and galea aponeurotica. The incision is held open with self-retaining retractor. **B.** A Hudson brace drill fitted with a perforator bit is used to penetrate the skull to the inner table. **C.** A hole has been made with the perforator bit. **D.** The hole is enlarged with a burr bit on the Hudson brace drill. **E.** The bone edges have been removed with a rongeur to expose the epidural hematoma. The hematoma is gently removed by suction.

after placement of the burr hole, inspect the underlying dura for a possible subdural hematoma. The presence of a subdural hematoma causes the dura to have a bluish hue or tinge (**Figure 144-9A**). Carefully place a traction suture in the middle of the exposed dura using 4–0 nylon (**Figure 144-9B**). Apply traction on the suture to elevate the dura. Incise the dura with a fine Mayo scissors or a #11 scalpel blade (**Figure 144-9B**). **Exercise extreme caution during the maneuver to prevent lacerating the brain.** Open the dura in a cruciate fashion. Drain the subdural clot using suction and gentle irrigation with normal saline. **At no time should any pressure be placed on the brain. Care should be taken not to irrigate with any force directly against the brain surface.**

FIGURE 144-9. Drainage of a subdural hematoma. **A.** The dura is exposed and a hematoma is visible below it. **B.** Traction is placed on a suture that has been placed through the center of the exposed dura. The tented dura is carefully opened with a scissors or scalpel to expose the underlying hematoma.

VENTRICULOSTOMY

The burr hole can be made in order to place a ventriculostomy catheter. Make a nick in the dura with an 18 gauge needle or a #11 scalpel blade. Perform a ventriculostomy using an appropriate ventricular catheter. Insert the catheter perpendicular to the skull and direct it toward the ipsilateral inner canthus to enter the ventricular system.¹⁸ Advance the catheter to a depth of approximately 5 to 6 cm. If unsuccessful after three attempts, place a parenchymal monitor or a subarachnoid bolt. Refer to Chapter 147 for the complete details of performing a ventriculostomy.

ASSESSMENT

Assessment and stabilization of the head injury victim prior to placement of the burr hole, during the procedure, and post-procedurally requires attention to securing the patient's airway, adequate and aggressive treatment of hemodynamic instability and shock, stabilization of the cervical and thoracolumbar spine, and concomitant treatment of any extracranial injuries. **Aggressive management of hypoxia and hypotension cannot be overemphasized. Hyperventilation in the first 24 hours after severe head injury should be avoided as it can reduce cerebral blood flow.** The assessment should include hemodynamic parameters, GCS, and frequent neurologic examinations. The neurologic examination should include pupillary size and reaction, extraocular muscle function, and motor movements of the extremities. Intubation using the rapid sequence technique often precedes burr hole placement in the patient with severe head injury. This precludes a detailed neurologic examination as most patients will have received neuromuscular blockade.

Reduction in pupillary size can be appreciated after evacuation of the hematoma in patients who have had pupillary changes preceding the burr hole placement. Repeat and document the hemodynamic and neurologic assessments every 5 minutes. Obtain a postprocedural CT scan of the head as early as possible to check the status of the hematoma. CT imaging also verifies catheter location and reduction in ventricular size in patients who have undergone ventricular catheter placement.

AFTERCARE

Patients who have had burr hole drainage require definitive management by a Neurosurgeon. A craniotomy is indicated for a more thorough evaluation, a thorough evacuation of the hematoma, irrigation of the epidural or subdural space, and hemostasis.^{19,20} Postprocedural CT imaging is not required if definitive management by a Neurosurgeon is available and the patient can proceed directly to the Operating Room. Cranioplasty is often postponed following burr hole drainage to minimize infectious risk. Postprocedural management often requires airway protection with continued endotracheal intubation, fluid resuscitation, management of hypoxia, management of hypotension, management of seizure prevention, and management of coagulopathy. Secondary injuries can evolve, even after adequate hematoma evacuation. They need to be anticipated, recognized, and treated aggressively.

A two-layer closure is recommended in the event a craniotomy is not to follow or will be delayed. The dura is usually not closed. Cover the dura with a small piece of thrombin-soaked Gelfoam. Close the galea with 3–0 absorbable suture. Close the scalp skin with 3–0 nylon suture. Apply a dry dressing to the scalp wound. Alternatively, apply sterile saline-soaked gauze over the wound and cover this with a dry dressing.

COMPLICATIONS

Wound infections, abscesses, hemorrhage, and postoperative hematomas are major complications.¹⁸ These can be avoided by using sterile precautions, antibiotic prophylaxis, and fine surgical technique. Other complications include plunging with the perforator bit or the burr bit and causing a penetrating injury to the brain, cortical laceration, or cortical contusion. Blunt or penetrating brain injuries can result in delayed stroke, hemorrhage, and seizures. Posttraumatic aneurysms and arteriovenous malformations have also been reported. A multitude of coagulopathic abnormalities can occur including disseminated intravascular coagulation, fibrinolysis, and hypercoagulability.

Significant bleeding complications can occur from the procedure.¹⁸ Penetration of the sagittal sinus can result in significant hemorrhage and possible exsanguination. Prevent this by staying at least 2 cm from the midline and properly identifying the landmarks before drilling into the skull. Avoid lacerating the middle meningeal artery or its branches. Prevent injuries to these arteries by not drilling beyond the inner table and carefully separating the dura from the skull before using the bone rongeur. Another option is to obtain a lateral plain radiograph of the skull. Note the position of the grooves in relation to the external auditory meatus. Avoid these grooves, and thus the branches of the middle meningeal artery, when determining the exact site to place the burr hole.

SUMMARY

The prognosis for the severely head-injured patient with clinical evidence of tentorial herniation and brainstem compression is poor. Rapid evacuation of an intracranial hematoma may help to improve

neurologic outcomes. Ideally, patients are resuscitated and a noncontrast CT scan of the head is performed in order to confirm the presence of an intracranial hematoma. Patients may at times undergo rapid neurologic deterioration prior to CT scanning or CT scanning may not be readily available. Diagnostic burr hole exploration and evacuation of an extra-axial hematoma can be a lifesaving measure. The authors do not wish to suggest that exploratory surgery should replace CT scanning in the management of patients with a severe head injury. The CT scan is invaluable in assessing and identifying the location of an intracranial hematoma. Burr hole evacuation in a trauma setting should be considered only in the presence of rapid neurologic deterioration, evidence of brain herniation, evidence of brainstem compression, and the unavailability of a Neurosurgeon to perform the procedure.

Lateral Cervical Puncture

Eric F. Reichman

INTRODUCTION

The safest procedure to obtain cerebrospinal fluid (CSF) is lumbar puncture. However, there are situations where lumbar puncture is either contraindicated or technically not feasible. This includes infections in the lumbar area, obesity, previous spinal surgery, previous spinal fusion, a history of arachnoiditis, and the previous injection of chemotherapeutics. The usual and safe alternative method is a lateral cervical puncture under such circumstances.

Cisternal puncture describes the suboccipital access to cisterna magna, a CSF-containing space. It is a less frequently used procedure due to the high incidence of complications. As a result, cisternal puncture should be performed by a Neurological Surgeon for patients whose CSF cannot be accessed by lumbar puncture or lateral cervical puncture.¹ It will be described in this chapter for the sake of completeness.

Dr. Mullan introduced a method for performing a percutaneous cordotomy using a lateral cervical puncture in the early 1960s.² He introduced a strontium-90 needle through the C1-C2 interspace and into the subarachnoid space under fluoroscopic guidance. He then directed the needle anteriorly toward the anterior dura mater to interrupt the spinal thalamic fibers in an attempt to control intractable pain. The lateral cervical puncture is a direct derivative of this technique.

ANATOMY AND PATHOPHYSIOLOGY

Lateral cervical puncture involves the placement of a spinal needle into the C1-C2 interspace, posterior and inferior to the vertebral artery. The vertebral artery ascends through the foramina in the transverse processes of the cervical vertebrae beginning at the sixth cervical vertebra. It winds behind the lateral mass of the atlas (C1) to enter the skull through the foramen magnum (**Figure 145-1**). Inserting the needle 1 cm inferior to the tip of the mastoid process and 1 cm posterior from that point will avoid puncturing the vertebral artery (**Figure 145-2**).

The spinal canal is formed by sequential vertebral foramina and is triangular in shape. Its lateral width is greater than the anteroposterior width. The spinal canal is more spacious in the upper cervical spine, allowing for safe placement of a needle into

the C1-C2 interspace. The sagittal diameter of the spinal canal is approximately 23 mm at C1 and 20 mm at C2. The cross-sectional area of the cervical spinal canal is greatest at C2 and progressively decreases. It is smallest at the level of C7. The vertebral canal is narrower in women than in men. The spinal canal at the level of C1-C2 can be divided into three parts. The anterior third is occupied by the odontoid process. The middle third is occupied by the spinal cord itself. The posterior third is occupied by the subarachnoid space. The spinal cord is suspended and cushioned within the subarachnoid space by CSF. The anterior boundary of the spinal canal is formed by the posterior aspect of the vertebral bodies and the intervertebral disks. The lateral wall of the spinal canal is formed by the pedicles and the intervertebral foramen. The posterior wall of the spinal canal is formed by the lamina, the ligamentum flavum, and the lateral masses or articular processes.

The morphology of the spinal cord demonstrates considerable individual variation in size and shape. The spinal cord changes in morphology throughout the entire spinal canal. It is cylindrical in shape and larger in transverse diameter than anteroposterior diameter. The spinal cord is largest from C3 to C6, obtaining approximately 13 to 14 mm in maximal transverse diameter. The average sagittal diameter of the cervical spinal cord is approximately 11 mm at C1 and 10 mm at C2.

The cervical nerve roots usually occupy the inferior one-third of the neural foramen. The first cervical spinal nerve root exits between the occiput and C1. The C2 through C7 spinal nerves exit above their corresponding numbered vertebra. Each nerve root innervates a specific dermatome and myotome, with considerable anatomic variation and overlap. The C1-C2 interspace is guarded laterally by the ligamentum flavum. The ligamentum flavum is composed of a yellow elastic tissue, the fibers of which are almost perpendicular in direction. It is attached to the lower part of the anterior surface of the lamina above and the posterior surface of the upper margin of the lamina below.

INDICATIONS

The lateral cervical puncture is an alternative method for obtaining CSF when lumbar puncture is not feasible or successful. Conditions that make lumbar puncture difficult are considered contraindications such as lumbar arachnoiditis, marked obesity, infections in the lumbar area, prior lumbar spine surgery, prior administration of lumbar intrathecal chemotherapeutics, and known congenital anomalies of the lumbar area (e.g., meningocele and myelomeningocele). The lateral cervical puncture is performed, like the lumbar puncture, in order to obtain CSF for analysis. CSF analysis

FIGURE 145-1. The course of the vertebral artery at the level of C1-C2. **A.** Posterior view. **B.** Lateral view.

FIGURE 145-2. Anatomic landmarks for the lateral cervical puncture. The site for insertion of the needle is represented by an ⊗.

is indicated in patients suspected of having a central nervous system infection or a subarachnoid hemorrhage. Other indications for lateral cervical puncture include the installation of antineoplastic or antimicrobial agents. Lateral cervical puncture may also be necessary for the introduction of dye for radiographic studies.^{3,4}

CONTRAINDICATIONS

Contraindications for a lateral cervical puncture include brain abscesses, brain tumors, cervical spine anomalies and deformities, coagulopathy, increased intracranial pressure, inflammatory adhesions, local infections, posterior fossa abscesses, posterior fossa tumors, thrombocytopenia, and vertebral artery anomalies (course or location). Arnold-Chiari malformations and other congenital abnormalities in the region of the foramen magnum are also a relative contraindication. These include achondroplasia, basilar impression, Dandy-Walker malformation, Klippel-Feil syndrome, and syringomyelia.

EQUIPMENT

- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Cap
- 20 gauge spinal needle with a stylette
- 23 gauge spinal needle with a stylette
- 3 mL syringe
- 20 gauge needles
- 22 gauge needles
- Three-way stopcock
- Manometer
- Extension tubing, optional
- Four specimen vials with caps
- Gauze pads
- Sterile towels
- Fenestrated sterile drape
- Lidocaine hydrochloride, 1%
- Sterile gloves
- Povidone iodine or chlorhexidine solution
- Fluoroscopy unit, optional

All of the basic equipment can be found in commercially available lumbar puncture kits. The kit needs to be supplemented with personal protective equipment and skin antiseptic.

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Obtain a computed tomography (CT) scan of the head if a complete neurologic examination cannot be performed or if it is abnormal in any way, the patient has a history of malignancy, or the patient may have a potential mass-occupying lesion (e.g., the patient with human immunodeficiency virus [HIV]). Obtain a complete blood count (hemoglobin, hematocrit, and platelet count) and a coagulation profile (prothrombin time, partial thromboplastin time, and international normalized ratio) to ensure that the patient is not thrombocytopenic or coagulopathic. Do not delay the administration of intravenous antibiotics pending these studies if meningitis is in the differential diagnosis and the reason for the lateral cervical puncture.

Explain the procedure, its risks, and benefits to the patient and/or their representative. Explain the postprocedural care. Obtain an informed consent for the procedure. Place the patient supine on the gurney, without a pillow, and the neck as straight as possible. Limit any head rotation from the true supine position. The landmark for needle insertion is 1 cm caudal and 1 cm posterior to the tip of the mastoid process (Figure 145-2).

This procedure requires strict aseptic technique. Clean the skin of any dirt and debris. Swab the area with alcohol pads. Shave the area so that the mastoid tip is contained within the sterile field. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Apply sterile towels and drapes to delineate a sterile field. Inject local anesthetic solution subcutaneously at the above identified landmark. Consider the administration of intravenous diazepam or midazolam, if not contraindicated, to relax the patient. Some patients may require the administration of procedural sedation. The aid of an assistant to hold the patient's head straight and upright is recommended.

TECHNIQUE

Maintain the patient in the supine position with absolutely no head movement. An assistant should stabilize the patient's head. Introduce a 21 or 22 gauge spinal needle perfectly horizontal, parallel to the plane of the bed, and perpendicular to the neck (Figure 145-3). The needle will cross a number of tissue planes including the skin, subcutaneous tissue, trapezius muscle, suboccipital muscles, and the meninges. Advance the needle slowly and in 2 to 3 mm increments. Remove the stylette frequently to check for CSF. The subarachnoid space is approximately 6 cm from the skin surface in most adults. Puncture of the dura is often felt as a "pop" or loss of resistance. Frequent checks for CSF prevent excessive penetration of the needle through the subarachnoid space, overshooting the spinal canal, or inadvertent puncture of the spinal cord or vertebral artery. **Immediately remove the spinal needle if the patient develops any neurologic symptoms.**

CSF flow through the needle signifies that the tip is within the subarachnoid space. If CSF is not draining after puncture of the dura and removal of the stylet, rotate the needle 30°. The use of a portable fluoroscopic unit can confirm the needle's trajectory and exact position. Carefully apply the three-way stopcock and manometer

FIGURE 145-3. Proper needle trajectory for a lateral cervical puncture.

to the spinal needle to measure the pressure of the CSF. Carefully remove the stopcock and the manometer from the spinal needle. **Do not allow the spinal needle to move while applying and removing the stopcock and manometer. Keep in mind that the needle is not very well supported by the soft tissue as in the lumbar puncture. Hence, the needle must be supported more carefully.** Collect 1 to 2 mL of CSF in each specimen tube. Insert the stylet into the spinal needle. Remove the spinal needle and stylet as a unit. Apply a bandage to the skin puncture site.

Encountering arterial blood from the spinal needle usually indicates that it was pointing too far anteriorly and that the vertebral artery was penetrated. The venous plexus surrounding the vertebral artery may also be penetrated. Remove the spinal needle and apply manual pressure if the vertebral artery is inadvertently entered. Reattempt the procedure with the tip of the spinal needle directed slightly more posteriorly. Directing the spinal needle too far posteriorly causes it to enter the spinal musculature and miss the spinal canal. In the event that bone is encountered, meaning that either the lateral arch of C1 or C2 is encountered, redirect the spinal needle slightly rostrally or caudally and advance it into the subarachnoid space.

ALTERNATIVE TECHNIQUE

The cisternal puncture is an alternative to the lateral cervical puncture. Place the patient in the lateral decubitus position on the gurney. Place a pillow under the patient's head to keep the cervical and thoracic spine as straight as possible. Limit any head rotation from the true position. **This procedure also requires strict aseptic technique.** Clean, prep, and anesthetize the skin from the external occipital protuberance to the mastoid process.

Maintain the patient in the lateral decubitus position with absolutely no head movement. An assistant should stabilize the patient's head. Flex the patient's head toward the chest while not moving the cervical spine. Introduce a 21 or 22 gauge spinal needle between the C2 spinous process and the occiput, aiming cephalad. The needle will cross a number of tissue planes. Advance the needle

slowly until the occiput is encountered. Slightly withdraw the needle and redirect it horizontally. Advance the needle in 2 to 3 mm increments until the cisterna magna is entered. The remainder of the procedure is as described for the lateral cervical puncture. The complications are similar to the lateral cervical puncture with the additional complication of laceration of the posterior inferior cerebellar artery.⁵

AFTERCARE

Maintain the patient in a supine position after the procedure. A small bandage is usually sufficient to control any soft tissue bleeding or continued CSF leakage. Postdural puncture headaches can be minimized by using a small gauged spinal needle inserted with the bevel parallel to the fibers of the dura. Resting in the supine position for 24 hours also reduces the incidence of postdural puncture headaches. Monitor the patient's neurologic status. Any change in patient's baseline neurologic examination requires a CT scan of the brain, posterior fossa, and occipital-cervical junction in order to rule out a herniation, epidural hematoma, or intradural hemorrhage.

Send the aspirated fluid for the appropriate laboratory analysis if an etiology other than an acute traumatic hemorrhage is suspected.⁶ This can include a biochemistry analysis (glucose and protein level), cell count and differential, culture (e.g., bacterial, fungal, viral), cytology, and Gram's stain.

COMPLICATIONS

The complications associated with lumbar puncture are also possible during the lateral cervical puncture. Specific complications from lateral cervical puncture include penetration of the vertebral artery with subsequent hematoma formation and puncture of the spinal cord with resultant neurologic deficits.⁶⁻¹¹ Minimize complications by using a small gauge spinal needle. These complications should result in no serious consequences if unilateral and recognized.⁶ Approximately 0.4% of the population has an anomalously positioned vertebral artery. There has been a single case report of a death from a subdural hematoma due to puncture of this vessel.⁷ A nerve root may be irritated with passage of the needle, resulting in local pain or possibly a headache. Other complications include infection, herniation syndromes, neck pain, and headache. The incidence of postdural puncture headache is less with the lateral cervical puncture than with a lumbar puncture. Refer to Chapter 142 for the complete details regarding the complications associated with a lumbar puncture. An ultrasound-guided technique has been described in animals.¹² This technique has not been described, as of the publication of this book, in humans.

SUMMARY

A lumbar puncture is still the preferred technique to obtain CSF for analysis as well as for injection of contrast material. The lateral cervical puncture is a safe alternative method. One can avoid the complications of puncturing the vertebral artery or the spinal cord by observing maximum attention to detail. The lateral cervical puncture can be performed at the bedside. However, the availability of a portable fluoroscopy or ultrasound unit can facilitate the procedure.

Intracranial Pressure Monitoring

Hannah Kirsch, Shahed Toossi, and Debbie Yi Madhok

INTRODUCTION

Increased intracranial pressure (ICP) can be a life-threatening result of brain injury (e.g., traumatic), edema (e.g., encephalopathy, post-operative, stroke, or trauma), expanding intracranial masses (e.g., abscesses, epidural hemorrhage, intraparenchymal hemorrhage, subdural hemorrhage, and tumors), hydrocephalus (e.g., aqueductal stenosis, Chiari malformation, or lesions obstructing cerebrospinal fluid [CSF] flow), infection (e.g., abscesses and meningitis), ischemic stroke, hemorrhagic stroke, metabolic abnormalities (i.e., encephalopathy, hypo-osmolality, and uremia), neurologic disorders, and pseudotumor cerebri. Elevated ICP can lead to disability, death, and permanent neurologic damage. It is often seen in the Emergency Department in relation to head trauma. High ICP may be seen just before death. Control of elevated ICP and fluctuations may improve recovery.

Most of this chapter is devoted to the current gold standard for ICP monitoring (i.e., ventriculostomy).¹⁻³ There are two basic types of ICP monitoring devices (**Figure 146-1**). One provides ICP data and the other provides ICP data and allows drainage of CSF. ICP monitors that use fluid are most accurate when closed to drainage. The methods of epidural, intraparenchymal, subdural, and ultrasonic ICP monitoring will be discussed briefly (**Figure 146-2**).

ANATOMY AND PATHOPHYSIOLOGY

The Monro-Kellie doctrine was conceived in the eighteenth century by Scottish Physician Alexander Monro and his pupil George Kellie. **The cranial vault contains a fixed volume. An increase in the volume of one or more cranial constituents (i.e., blood, brain, and CSF) must be compensated for by a decrease in another constituent(s).** There is a balance between these components,

A

B

C

FIGURE 146-1. Examples of ICP monitoring devices. **A.** ICP monitor device. **B.** ICP monitoring device with CSF drainage. **C.** ICP "bolt"

making a dynamic equilibrium. The brain parenchyma is virtually incompressible. Backflow of CSF through the cerebral aqueduct and the relative vasoconstriction of cerebral vessels occurs after an acute brain injury to compensate.⁴ Examples are the presence of

FIGURE 146-2. Locations of ICP monitoring devices. (Used with permission from reference 3.)

extravascular blood or edematous brain parenchyma.⁴ There can be an abrupt increase in ICP once the initial compensatory shifts in blood volume and CSF are maximized (**Figure 146-3**).⁵

The elevation in ICP can result in herniation or shifting of brain tissue from an area of high pressure to an area of low pressure. Infratentorial mass effect can eventually lead to tonsillar herniation without appropriate pressure relief. Supratentorial mass effect can eventually lead to transtentorial herniation without appropriate relief of pressure. Herniation of the temporal lobe uncus can cause altered mental status and ipsilateral pupillary dilation. The less common central herniation causes bilateral pinpoint pupils and weakness. Tonsillar herniation may occur suddenly with examination signs of cardiac instability, coma, pinpoint pupils, and respiratory instability.⁴

One of the primary goals of ICP monitoring is to maintain an optimal cerebral perfusion pressure (CPP) that delivers the appropriate cerebral blood flow (CBF). Normal CBF averages 55 to 60 mL/100 gm brain tissue/min. The CBF is higher in gray matter (i.e., 75 mL/100 gm brain tissue/min) and lowest in white matter

FIGURE 146-3. Intracranial pressure is relatively stable over a range of increasing volume of intracerebral contents. ICP begins to increase exponentially above this range.

FIGURE 146-4. CBF is approximately constant between MAPs of 50 and 150 mmHg in a healthy individual without long-standing hypertension. Cerebral arterioles (represented along the top) can no longer change size to regulate flow over a MAP of 150 mmHg.

(i.e., 45 mL/100 gm brain tissue/min). CPP is vital to supporting cerebral perfusion. A CPP of 60 to 70 mmHg is adequate for maintaining brain functions. CPP is calculated as mean arterial pressure (MAP) – ICP. MAP is calculated as the diastolic blood pressure plus one-third of the pulse pressure or two-thirds of the diastolic blood pressure plus one-third the systolic blood pressure. CBF is calculated as CPP divided by cerebrovascular resistance. CBF can be maintained at a near constant level over a MAP range of about 50 to 150 mmHg by manipulating arteriolar diameter, which dictates cerebrovascular resistance (**Figure 146-4**). **This is the principle of cerebral autoregulation.**⁶ CBF is insufficient to adequately perfuse tissue and can cause ischemic injury when below this MAP range. The CBF increases directly with MAP and can cause injury from hyperperfusion and elevated ICP by increasing the amount of blood volume in the brain when above this MAP range. Vasoconstriction decreases the CBF and cerebral blood volume.

The normal ICP ranges up to 20 mmHg. The range of 15 to 20 mmHg is abnormal and > 20 mmHg is pathologic. ICP elevation for more than 5 minutes is referred to as sustained intracranial hypertension. The monitor catheters can be used for several days before requiring replacement. The normal ICP waves have a steep upward slope during systole and a dicrotic notch during the downstroke in diastole (**Figure 146-5**). This indicates normal ICP.

External ventricular drains (EVDs) and other monitors provide the absolute measure of ICP and the ICP waveforms. Interpret the waveforms to provide additional context to the ICP measurement (**Figure 146-5**).⁵ A normal ICP waveform has three upstrokes, each with a lower amplitude than the preceding one. The percussion wave (i.e., P1) corresponds to systole. It represents choroid plexus pulsations. It is normally the tallest of the three types of waves. The tidal wave (i.e., P2) corresponds to intracranial compliance. It represents brain volume and can be variable in shape. It is elevated in response to a rapidly increasing mass in the cranial cavity. A P2 wave higher than P1 represents decreased intracranial compliance. The dicrotic wave (i.e., P3) corresponds to the aortic valve closing. This is the lowest of the three waves normally.

ICP waveforms can be recorded with trend recording (**Figure 146-6**). A-waves or plateau waves have an amplitude of 50 to 100 mmHg above baseline and last up to 20 minutes. They are associated with decreased consciousness, increased extremity tone,

FIGURE 146-5. The normal ICP waveform is contrasted with an ICP waveform in the setting of decreased intracranial compliance.

restlessness, and tonic-clonic movements. They may represent surges in ICP due to increased cerebral blood volume. B-waves have an amplitude of 10 to 20 mmHg above baseline and are short lasting (i.e., < 2 minutes). They often precede A-waves, correlate with respiratory changes, and increasingly occur in decompensation. C-waves or Traube-Meyer-Hering waves are low amplitude, rapid, and may be superimposed on other waves. They can be seen with normal or increased ICP and fluctuate with respirations and changes in blood pressure.

Intracranial compliance is the ability of the brain to tolerate stimulation in other body regions and the accommodative potential of the intracranial space. It can be assessed by several methods. Injection of 1 mL aliquots of preservative-free saline into the intracranial vault and the ICP is measured. An increase of 2 mmHg or more for each 1 mL injected indicates compromised intracranial compliance. ICP can be measured before and after an external stimulus (e.g., endotracheal intubation). The ICP should return within 5 minutes to baseline, which indicates appropriate intracranial compliance. The ICP waveforms can be examined. An elevated P2 can be seen with impaired intracranial compliance.

One strategy to decrease ICP and deliver an optimal CPP is to augment the MAP to trigger the brain to vasoconstrict arterioles and decrease the total blood volume in the closed cranial vault. This only works with a brain with an intact cerebral autoregulation

INDICATIONS

The neurologic physical examination is the cornerstone of assessing whether a patient requires ICP monitoring. The Brain Trauma Foundation and European Brain Injury Consortium guidelines state that ICP monitoring is indicated in traumatic brain injury patients with an abnormal head computed tomography (CT) scan and Glasgow Coma Scale score less than 9 after resuscitation.⁷ An abnormal CT scan is defined as intracranial contusions, diffuse edema, and hematomas. ICP monitoring is indicated in patients with severe traumatic brain injury and a normal CT scan with asystolic blood pressure < 90 mmHg, age over 40, or motor posturing (i.e., unilateral or bilateral).⁷ The latter recommendation is based on a 1982 study regarding the risk of intracranial hypertension in patients with normal versus abnormal initial CT scans.⁸

Nontraumatic brain injury (e.g., hemorrhagic or ischemic stroke) requires ICP monitoring when the patient has a decline in alertness and signs of impending herniation. Anticipatory monitoring is useful in patients when sedation and/or paralysis impedes the physical examination assessment. Consider an anticipatory ventriculostomy in patients with injuries that are at high risk of progression to elevated ICP (e.g., extensive intraventricular hemorrhage or subarachnoid hemorrhage).

Interventricular catheters, commonly called EVDs, are considered the gold standard for ICP measurement. They are the only monitoring method that allows simultaneous measurement of ICP and treatment of elevated ICP via CSF drainage.⁹ A less invasive monitoring option is an intraparenchymal device placed through a so-called "bolt" in the skull that can provide simultaneous access for other types of monitoring (e.g., cerebral blood flow). Recalibration of the zero point is not possible with these devices. A drift in the zero point is calculated as the difference between the ICP recorded after a device is removed and zero ICP measured while the device is in place and is a concern. Several observational studies have suggested that zero drift is not as significant a problem as first anticipated.^{10,11} Most recent studies show accuracy ranges from 2 to 7 mmH₂O when compared to intraventricular pressures.^{9,11-14} Hemorrhage and infection rates are comparable to those of intraventricular catheters, and numerous studies suggest lower complication rates.^{9,15} One of the biggest disadvantages of this type of monitor (i.e., a "bolt") compared to an EVD is the inability to divert CSF. Subdural and epidural monitoring devices have been developed as less invasive options.

FIGURE 146-6. Examples of ICP waveforms using trend recording. (Used with permission from www.clinicalgate.com.)

Their accuracy is more limited than that of intraparenchymal devices. Their use is plagued by zero drift and frequent dislodging after placement. These devices are not frequently used.

CONTRAINDICATIONS

Contraindications for ventriculostomy specifically include the presence of increased intratentorial pressure without an occipital craniectomy, which may induce upward herniation if intraventricular pressure is relieved. Other general procedural contraindications include thrombocytopenia and coagulopathy. There are no validated guidelines. Typical acceptable parameters include an international normalized ratio (INR) of up to 1.6 and platelets of less than 100,000/ μL .^{16,17} Emergent platelet transfusion or administration of fresh frozen plasma may be warranted under these circumstances. Perform a noncontrast head CT scan prior to ICP monitor insertion to ensure that there is no hemorrhage, mass, or other lesion along the anticipated tract.

EQUIPMENT

- ICP monitor (Table 146-1)
- Skull penetration equipment (Chapters 144 and 147)
- External monitoring device (Figure 146-7)
- Sterile gloves
- Sterile gown
- Cap
- Face mask with eye shield or goggles

■ ULTRASOUND (US) EQUIPMENT

- US machine
- US gel
- High-frequency US transducer
- Clear adhesive dressing (e.g., Tegaderm)

The Codman Microsensor can read intraparenchymal, intraventricular, and subdural pressure depending on its location. It drains CSF if placed in the ventricle. It uses a strain gauge located at the tip and transmits pressure changes over a diaphragm.

The Gaeltec ICP monitor measures ICP subdurally. This system is reusable. It measures pressure with a balloon-covered sensor.

The Integra Neuroscience products are most numerous. Some systems allow CSF drainage and ICP data. The drain must be leveled with the foramen of Munro, zero-balanced daily, and its level adjusted to regulate flow. Other systems measure ICP data without CSF

drainage. These systems use a diaphragm to measure pressure or a transducer.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the ICP catheter insertion on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Maintain sterility of the ICP catheter and skull entry site. This includes accessing CSF through the catheter. Don full personal protective equipment before placing the ICP catheter. Use a cap, face mask, and sterile gloves if accessing the CSF through the ICP catheter or maintaining the skull puncture site.

Note and document the physical examination with an emphasis on the nervous system. Early signs and symptoms of elevated ICP include altered mental status, headache, nausea, and vomiting. **Note the vital signs frequently.** This can progress to coma and motor posturing in response to noxious stimuli. Cushing's response (i.e., the triad of bradycardia, irregular respirations, and systolic hypertension) may be present. Document the patient's alertness and Glasgow Coma Scale score (Tables 146-2 and 146-3). Note language articulation, comprehension, fluency, and repetition. Assess the corneal reflexes, extraocular movements, pupillary response, and visual fields. Document the blinking, presence of doll's eyes, and visual pursuit if the patient does not follow commands. Examine the fundus for changes to the optic nerve suggestive of papilledema and increased ICP (e.g., changes of the blood vessels, changes to the cup-to-disk ratio, and changes to disk margins). Perform and document the vital signs frequently.

INVASIVE TECHNIQUES

A full technical description of EVD placement in adult and pediatric patients is detailed in Chapter 147 titled "Ventriculostomy." The directions below will vary depending on the exact model of the ICP monitor. The advantages and disadvantages of these invasive techniques are listed in Table 146-4. The invasive techniques are more accurate than noninvasive techniques.¹⁸⁻²¹ The general instructions are below.

Insert the ICP device using sterile conditions. Connect all cables. Connect the cable to the ICP cable in the patient's skull. Connect the other end of the cable to the external monitor. Turn the external monitor on. Zero the external monitor. Calibrate the patient monitor. Begin measuring the quantitative ICP and waveforms.

NONINVASIVE TECHNIQUES

These techniques can be used to estimate the ICP.¹⁸⁻²¹ They are not as accurate as invasive techniques.

OPTIC NERVE SHEATH DIAMETER

The diameter of the optic nerve sheath can be used to estimate ICP.²²⁻²⁶ This can be performed using CT scans or US.^{19,18-30} The bony eye socket and the fluid-filled globe are suited for US examination. Papilledema is visualized as a hyperechoic protrusion from the optic disk.²³ Increased ICP is transmitted through the subarachnoid layer to the optic nerve sheath. This results in an enlarged optic nerve sheath.²² The advantages of using US are as follows: it is convenient, easily learned, and easy to perform at bedside; it lacks ionizing radiation; and it can be performed without moving the patient to the CT scanner. Papilledema is uncommon in acute ICP elevations

TABLE 146-2 The Glasgow Coma Scale Score*

Score	6	5	4	3	2	1
Eye opening	N/A	N/A	Spontaneously	In response to speech	In response to painful stimuli	Do not open in response to stimuli
Motor response	Follows commands	Localized movement to painful stimuli	Nonpurposeful movement to noxious stimuli	Flexes upper extremities and extends lower extremities to painful stimuli	Extends all extremities to painful stimuli	No response to stimuli
Verbal response	N/A	Orientated to person, place, and time	Converses but confused	Replies inappropriately	Incomprehensible	No response

*The total score is the sum of the eye opening, motor response, and verbal response components. N/A, not applicable.

TABLE 146-3 The Pediatric Glasgow Coma Scale Score*

Score	6	5	4	3	2	1
Eye opening > 1 year old	N/A	N/A	Spontaneously	In response to speech	In response to painful stimuli	Do not open in response to stimuli
Eye opening < 1 year old	N/A	N/A	Spontaneously	In response to shouting	In response to painful stimuli	Do not open in response to stimuli
Motor response > 1 year old	Follows commands	Localized movement to painful stimuli	Flexion; withdraws to painful stimuli	Flexes extremities to painful stimuli	Extends extremities to painful stimuli	No response to stimuli
Motor response < 1 year old	Follows commands	Localized movement to painful stimuli	Flexion; withdraws to noxious stimuli	Flexes extremities to painful stimuli	Extends extremities to painful stimuli	No response to stimuli
Verbal response > 5 years old	N/A	Orientated to person, place, and time	Converses but confused or disoriented	Replies inappropriately	Incomprehensible	No response
Verbal response 2–5 years old	N/A	Appropriate words or phrases	Inappropriate words	Persistent cries and screams	Grunts	No response
Verbal response < 2 years old	N/A	Smiles or coos appropriately	Cries inconsolably	Persistent inappropriate crying and/or screaming	Grunts, agitated, and restless	No response

*The total score is the sum of the eye opening, motor response, and verbal response components. N/A, not applicable.

TABLE 146-4 Advantages and Disadvantages of ICP Methods

ICP monitor	Advantages	Disadvantages
Epidural	Decreased risk of infection Easily placed Least invasive method Quickly placed	Cannot determine pressure–volume relationship Decreased accuracy of ICP Decreased waveform quality Increased baseline drift with time No CSF drainage or sampling
Intraparenchymal	Baseline drift of 1 mmHg per day Easily placed Easy to move patient location Good-quality waveforms Less artefact than other devices No need for adjustment with patient position changes Only requires zeroing during insertion Uses fiberoptic transducer at tip	Baseline drift if used for multiple days Cannot be recalibrated after placement Cannot determine pressure–volume relationship Easily damaged Fragile cable Manipulation can damage fiberoptics No CSF drainage or sampling Requires periodic replacement
Intraventricular	Accurate ICP measurements Can determine pressure–volume relationship Contrast administration CSF drainage to decrease ICP CSF sampling Medication administration	Bleeding with quick CSF drainage Catheter occlusion CSF leakage Difficult insertion with compressed ventricles Difficult insertion with displaced ventricles Difficult insertion with edema Difficult insertion with small ventricles Frequent transducer recalibration Infection to center of brain Ventricle collapse with quick CSF drainage Very invasive
Subarachnoid	Easily placed Can be used with collapsed or small ventricles Lower infection rates than ventricular catheters No brain penetration No locating ventricles Quickly placed	Dampened waveforms Less accurate than other methods Frequent recalibration No CSF drainage or sampling Recalibration after patient position changes
Subdural	Same as epidural	Same as epidural

and is often a late sign of elevated ICP. A normal optic nerve sheath does not exclude elevated ICP. The normal optic nerve sheath diameter will vary among patients and the normal values are difficult to define.

The patient can be in any position. The pediatric patient can be restrained (Chapter 232) or held by a parent. Have the patient close the eye. Apply a clear dressing over the eye to keep the eyelid closed. This also decreases the anxiety of the transducer approaching and pushing on the eye. It also prevents the US gel and transducer from irritating the eye or causing a corneal abrasion. Apply US gel liberally to obtain a good acoustic window and prevent any pressure on the eye. Scan the eye in the longitudinal and transverse planes. Scan the eye with the patient looking in four directions to find the best optic nerve sheath dimensions. Looking inward often moves the optic nerve the most perpendicular to the US waves.²⁸

TRANSCRANIAL DOPPLER

Transcranial Doppler (TCD) can be used in children, sedated patients, trauma patients, and when invasive ICP monitoring is contraindicated.²⁷ TCD can be performed at the bedside, is non-invasive, and is portable. It measures cerebral blood flow velocities. TCD relies on operator-dependent factors (e.g., locating the acoustic window, the angle of the transducer, and obtaining a strong pulse signal). It may be difficult to obtain a sufficient Doppler signal limiting the use of TCD.

OCULAR VASCULATURE

Third Eye Diagnostics Inc. of Bethlehem, Pennsylvania, has developed the Cerepress. It uses the blood vessels of the eye to estimate ICP. It noninvasively measures blood pressure in the central retinal vein as a correlate to ICP. The Cerepress measures intraocular pressure and ICP. This hand-held device can be used at bedside and requires little training.

ASSESSMENT

Perform a noncontrast head CT to confirm accurate placement of the ICP monitor. Hemorrhage along the insertion tract may or may not become clinically significant. Repeat the CT scan if hemorrhage is present to ensure the stability of hemorrhage size. The EVD and other monitors provide the absolute measure of ICP and the ICP waveforms. Interpret the waveforms to provide additional context to the ICP measurement (**Figures 146-5 and 146-6**).⁵

AFTERCARE

Monitor all patients requiring invasive ICP monitoring in an Intensive Care Unit. Closely monitor hemodynamic and respiratory status. Perform frequent examinations of the patient's vital signs and neurologic examinations as noted in the patient preparation section earlier (**Tables 146-1 and 146-2**).

COMPLICATIONS

Major complications are hemorrhage and infection. Tract hemorrhage upon catheter insertion and removal occurs between 5% and 41% of patients.³¹⁻³⁴ The rate of clinically significant hemorrhage is low and ranges from 0.5% to 5% of patients. Studies on hemorrhage rates are limited and most are retrospective.

There is a wide range of reported incidences of ICP device-associated infection (e.g., abscesses and meningitis).^{14,35-37} Infection rates are associated with a longer duration of monitoring. Sterile technique reduces the risk of infection. **Use sterile technique**

when placing a ventricular catheter. Some retrospective studies showed an increased risk of infection in devices inserted outside the Operating Room. These differences were not statistically significant. Staphylococci are the most common bacteria isolated. There is mixed evidence for the use of single-dose antibiotic prophylaxis at the time of ICP catheter insertion.^{38,39} Consult institutional guidelines prior to performing the procedure regarding antibiotic administration.

Technical issues can lead to inaccurate ICP measurements. Zero-balance the catheters daily and whenever the catheter is moved. Catheters can become occluded with arachnoid villi, brain tissue, or blood clots. Waveforms can be dampened by clots, by air in the catheter, or if the catheter tip is against the brain. Catheters can bend or kink. Waveforms can be misinterpreted.

SUMMARY

Patients with traumatic brain injury or other pathology often require monitoring of ICP in response to signs of intracranial hypertension (e.g., clinical or radiologic) or in anticipation of impending elevations of ICP. EVDs are the gold standard method of ICP monitoring and a way to relieve elevated pressures via CSF drainage. Less invasive methods of monitoring are currently less accurate and largely confined to more specialized centers but may become more reliable and accessible in the future.

Ventriculostomy

John Burke, Shahed Toossi, and Debbie Yi Madhok

INTRODUCTION

An external ventricular drain (EVD) is the gold standard for measuring intracranial pressure (ICP) because it is both diagnostic and therapeutic.¹ Elevated ICP can be quickly ascertained and subsequently relieved by draining cerebrospinal fluid (CSF) through the EVD catheter. Occasionally, placement of an EVD represents an emergent lifesaving procedure that needs to be done within minutes in a patient who is deteriorating rapidly from a neurologic perspective.² This chapter will discuss some of the situations when this procedure may be considered, other therapeutic options, and an explanation of how to perform an emergent ventriculostomy.

ANATOMY AND PATHOPHYSIOLOGY

The cranium is a fixed space after infancy that has little capacity for added volume or mass. This concept is the fundamental principle behind the Monro-Kellie doctrine which states that the fixed space of the skull must accommodate brain tissue, blood, and CSF. **An increase in volume of any one of these substances without a compensatory decrease in the amount of the other will lead to an increase in ICP.** All states of increased ICP can be understood within this framework. Examples include tumors that may increase ICP either by adding volume to the cranium (i.e., the mass itself), blocking CSF outflow (i.e., increasing the amount of CSF), causing vasogenic edema (i.e., expanding the amount of brain tissue), hemorrhaging into the tumor cavity (i.e., increasing the amount of blood in the cranium), or any combination of these mechanisms. Other pathologic conditions including edema, infection, intracranial hemorrhage, and massive cerebral infarctions can increase ICP.

The patient with increased ICP may display the classic clinical signs of headache, vomiting, and papilledema.² Vomiting is particularly associated with acute increases in ICP. Other signs include a cranial nerve VI (i.e., the abducens nerve) palsy that causes diplopia, decreased consciousness, and an elevated blood pressure with bradycardia (i.e., Cushing's phenomenon). **An increase in ICP may eventually progress to herniation which occurs when there is a force applied to a part of the brain great enough to push other parts of the brain into different cranial compartments.** The cranial contents are divided into compartments by invaginations of the dura mater (**Figure 147-1**).³ The supratentorial space is separated from the infratentorial space by the tentorium cerebelli. The right and left hemispheres are separated by the falx cerebri.

When a unilateral supratentorial mass exerts enough force, the ipsilateral cerebral hemisphere is pushed medially toward the opposite hemisphere (**Figure 147-2A**). A tentorial herniation is when the medial aspect of the temporal lobe is pushed down toward the brainstem and over the edge of the tentorium cerebelli (**Figure 147-2B**). The symptoms of a tentorial herniation include a worsening of any headache with vomiting, progressively decreasing consciousness, anisocoria, hemiparesis, and Parinaud's syndrome (i.e., an upward gaze paresis) from compression on the dorsal midbrain. Compression of the oculomotor nerve results in a sluggish and dilated pupil, usually on the same side as the mass lesion. **A progression to a fixed and dilated pupil with decerebrate rigidity (i.e., extensor posturing) is an ominous sign of increased ICP.**

Mass effect in the infratentorial compartment of the skull may produce downward pressure of the cerebellum into the foramen

FIGURE 147-1. The falx cerebri and tentorium cerebelli divide the skull into compartments. **A.** Sagittal view. **B.** Coronal view. **C.** Top of the skull removed with a section of tentorium cerebelli also removed.

magnum (**Figure 147-3A**) or upward pressure of the midbrain into the supratentorial compartment (**Figure 147-3B**), the former being more common. The downward pressure is known as tonsillar or cerebellar herniation (**Figure 147-3A**). The terminal events surrounding this condition may occur more urgently and fatally than a supratentorial herniation. The urgency of cerebellar herniation stems from both the tight space in the posterior fossa compared to the supratentorial compartments as well as the vital structures found in this area. For example, an acute respiratory arrest may occur from compression of the medulla. Other important signs of tonsillar herniation include profuse vomiting, irregular respirations (e.g., ataxic breathing), neck pain, and neck stiffness. **The patient**

may not necessarily lose consciousness or have pupillary changes prior to the terminal events of tonsillar herniation. Upward herniation forces the cerebellum and upper brainstem through the tentorial notch (**Figure 147-3B**). The patient is usually obtunded or comatose with small or anisocoric pupils that may at first be reactive. There may be an associated paresis of the extremities which progresses to decorticate posturing.

Any patient with these potentially life-threatening neurologic findings should be considered unstable and worked up accordingly. An emergent head computed tomography (CT) scan is the diagnostic test of choice after the patient's airway, breathing, and circulation have been stabilized. The signs of subfalcine herniation on the head

FIGURE 147-2. Herniation of the brain. **A.** Subfalcine herniation. **B.** Tentorial herniation.

FIGURE 147-3. Herniation of the brain. **A.** Downward cerebellar tonsillar herniation through the foramen magnum. **B.** Upward cerebellar herniation into the supratentorial compartment.

CT include an anterior midline shift with brain tissue from one side pushed under the falx and into the opposite side of the brain (**Figure 147-2A**). Other signs include generalized cerebral edema with effacement of the sulci, the ventricles, the basilar cisterns, and the fourth ventricle.

The term herniation is often confused with mass effect. These are two terms for independent variables. Herniation is an emergent clinical syndrome that portends acute neurologic decompensation and implies a rapid onset of symptoms. Mass effect and increased midline shift are radiologic phenomena that may or may not correlate with the clinical syndrome of herniation. For example, a well-compensated chronic increased ICP may not directly lead to herniation despite the radiologic presence of a mass effect. Clinical status is the best predictor of herniation and is the most important indicator for the emergent placement of an EVD. A patient with a Glasgow Coma Score of 15 will rarely require an EVD no matter what the head CT shows.

There are several clinical interventions that should be implemented immediately once increased ICP, hydrocephalus, or herniation is suspected and the patient's condition is declining.⁴ The airway must be stabilized and rapid sequence intubation is the procedure of choice. Pretreatment with lidocaine may be useful in diminishing the elevation in ICP that occurs during direct laryngoscopy. Propofol and etomidate are the induction agents of choice as they may decrease the ICP. Thiopental is another choice but is rarely used in the United States due to it causing hypotension. There is a theoretical risk that ketamine can increase ICP secondary to increasing cerebral blood flow and increasing cerebral metabolic rate of oxygen. There is a dearth of evidence supporting these possibilities.⁵ An advantage to ketamine is that it is more hemodynamically stable than both etomidate and propofol. Neuromuscular blockade is accomplished with succinylcholine after administering a defasciculating dose of a nondepolarizing neuromuscular blocking agent. Paralytics may only be necessary for a brief period during intubation. **It is preferable to avoid paralysis for any length of time when the patient's neurologic status needs to be followed closely and any changes readily identified.** However, the need to follow the patient's neurologic course should be balanced by the need to reduce elevated ICP that may be accomplished, in part, with sedatives and paralytics. The potential for succinylcholine increasing ICP is most prevalent in patients with neoplasms of the central nervous system and may not be significant for acute trauma or bleeds.⁶ Maintain the patient's oxygen saturation at 100%. The importance of avoiding unnecessary sedatives and paralysis cannot be overstated, as the most important determinant of whether a patient needs an EVD is the clinical exam. Basic maneuvers to control increased ICP should always be implemented including elevating the head of the bed to 30° or placing the patient in the reverse Trendelenburg position if a cervical spine injury is suspected.

It is desirable for the initial cerebral perfusion pressure (CPP) to be 60 mmHg or higher to diminish the risk of cerebral ischemia. The lower limit of an acceptable mean arterial blood pressure (MAP) is usually 70 to 80 mmHg.⁷ Higher MAP goals may be indicated if the patient has elevated ICP with an intact cerebral autoregulation. Hyperosmolar therapy with an osmotic diuresis and a induced hyponatremia are commonly used with the effectiveness of the former dependent on adequate renal function. Hyperventilation to reduce the $p\text{CO}_2$ in the range of 30 to 35 mmHg can reduce ICP in the acute resuscitation phase by causing arterial vasoconstriction with lower $p\text{CO}_2$ goals increasing the risk of cerebral ischemia. **Hyperventilation to lower ICP should only be used for a short time as a bridge to another ICP management strategy given the risk of causing rebound intracranial hypertension once the brain pH equilibrates.** The use of osmotic diuretics, such as mannitol,

can reduce ICP quickly. Unfortunately, any extended duration of use of osmotic diuretics places the patient at an increased risk for cerebral ischemia. Other methods to consider include the use of dexamethasone in patients with edema surrounding a neoplastic mass or abscess. Barbiturates such as pentobarbital and phenobarbital can be used to induce a coma and reduce ICP by decreasing the cerebral metabolic rate of oxygen but cause hypotension. Paralysis decreases intrathoracic pressure and facilitates venous drainage from the brain resulting in lower ICP. **It is imperative that an ICP monitoring device is put into place since the ability to do sequential neurologic checks is lost if barbiturates or paralysis are employed as a means of lowering ICP.** Consider obtaining an electroencephalogram. The commonly used modality of osmotic diuresis is still used in the acutely deteriorating patient but is limited because of the ischemic and metabolic complications related to its use.⁸

INDICATIONS

The primary indication for a ventriculostomy is to decrease elevated ICP unresponsive to less invasive management methods.⁹ The presence of an EVD and the management of ICP have been shown to decrease mortality.¹⁰ This may change in the future if other studies show no benefit.¹¹ Care of the traumatic brain injury did not show keeping ICP by monitoring at 20 mmHg and or less to be superior to care based on imaging and examination.¹¹ A ventriculostomy can also be performed to measure ICP, drain CSF to treat hydrocephalus, introduce contrast for radiographic studies, or collect CSF from the ventricular system.¹²

It is preferable to treat an identifiable pathologic process as soon as possible. This usually requires intervention by a Neurosurgeon. The Neurosurgeon may be able to take the patient to the Operating Room to place an indwelling ventricular shunt system in an expedited fashion.¹³ The ICP can be monitored and reduced by draining CSF via a ventriculostomy in the Emergency Department if the patient continues to deteriorate and a definitive procedure cannot be immediately arranged.¹⁴

CONTRAINDICATIONS

Performing a ventriculostomy could precipitate or worsen brain herniation and hasten the patient's mortality if an infratentorial mass has been identified and it appears to be inducing upward pressure into the supratentorial compartment. A coagulopathy or thrombocytopenia makes a ventriculostomy dangerous to perform. The use of anticoagulants and antiplatelet agents by the patient increases their risk of hemorrhagic complications. Consider reversing these conditions by administering fresh frozen plasma and/or platelets prior to performing a ventriculostomy. A mild elevation in the international normalized ratio (INR) up to 1.6 may be acceptable to place a ventriculostomy.¹⁵

EQUIPMENT

- Skin razor
- Skin prep kit with povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Cap
- Skin marker
- Ventricular catheter with stylet
- Tunneling device for catheter
- Drainage tubing and collection system

- Measuring implement (e.g., ruler)
- Scalpel handle
- #15 and #11 scalpel blade
- 10 mL syringe
- 25 gauge needle
- Lidocaine with epinephrine, 1%
- Self-retaining retractor
- Twist drill with a ¼ inch bit
- Sterile towels or drapes
- Bipolar cautery
- Needle driver
- 3–0 nylon suture
- Suction source
- Suction tubing
- Suction catheters
- Pressure transducer
- Blunt tip catheter to probe palpate the dura, optional
- Spinal epidural needle to puncture the dura, optional
- Headlight, optional
- Curette, optional
- Three-way stopcock, optional

It is most useful to have either a commercially available ventriculostomy kit or assemble one to have available in the resuscitation area. Complete, disposable, and single patient use kits are convenient and cost-effective (Figure 147-4).

PATIENT PREPARATION

This procedure is often performed emergently. Explain the procedure and its risks and benefits to the patient and/or their representative if possible. Explain the general surgical risks and the risk of placement-related hemorrhage. If it will not unduly delay the treatment, obtain an informed consent to perform the procedure.

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor if available. Before the procedure, it is important to implement four steps summarized by the 4-C

FIGURE 147-4. An example of the contents of a commercially available ventriculostomy kit.

mnemonic of consent, coagulation labs, coagulation medications, and CT scanning. Coagulation medications should be reviewed, as the presence of anticoagulation medications (e.g., warfarin) or antiplatelet medications (e.g., aspirin) significantly increases the chance of a symptomatic placement-related hemorrhage and may alter the risk-benefit profile of the procedure. Obtain a complete blood count (i.e., hemoglobin, hematocrit, and platelet count) and a coagulation profile (i.e., prothrombin time, partial thromboplastin time, and INR) to ensure that the patient is not thrombocytopenic or coagulopathic. These may require reversal with the administration of fresh frozen plasma, prothrombin complex concentrate, and/or platelets. The head CT should be reviewed. It can determine the presence of an acute subdural or epidural hematoma and the location and extent of the hematoma, rule out the presence of a mass, and determine if there is any herniation. The head CT can be used to obtain measurements that aid in the placement of the EVD. This includes the presence of a midline shift, the distance from the skull to the ventricles, and the distance to the foramen of Monro.

Set up the room and collect the necessary equipment. **Position the patient so their head is at the edge of the bed, the head of the bed is elevated to facilitate drilling and catheter placement, and there is adequate space for the Emergency Physician to work.** Perform a “time out” to confirm the side of the procedure, that consent was received, and that the CT and laboratory studies were reviewed. Shave the patient’s head for 4 to 5 cm surrounding the burr hole entry point. The hair from the entire frontal area back to the ear may be shaved, but it is probably unnecessary.

Identify Kocher’s point.^{16–20} Kocher’s point is found by identifying the glabella and measuring 10.5 cm posteriorly in the midline. Mark the point 2.5 cm laterally from the end of the line 10.5 cm posterior in the midline to identify Kocher’s point (Figure 147-5). The final entry point should be centered in the midpupillary line. This is approximately 1 cm anterior to the coronal suture in the midpupillary line (Figure 147-5).

Clean the skin of any dirt and debris. Cleanse the area once with a chlorhexidine swab. Inject local anesthetic solution with epinephrine at the site of the entry. Inject local anesthetic solution with epinephrine over the forehead to block the innervation from the V1 branches providing sensation to the scalp in this region. Repeat the prep of the scalp with povidone iodine and allow it to dry. Dress in full sterile attire (i.e., hat, mask, eye shield or goggles, sterile gown, and sterile gloves). Drape the field using sterile towels or prefabricated drapes. **It is imperative that strict sterility is maintained throughout the procedure. When creating the sterile field, it is important that proper aim of the catheter is obtained before insertion. It is necessary to have the ipsilateral medial canthus and the tragus fully visualized in the skin preparation or for marks to these structures to be made before the skin preparation with a sterile marker to allow the proper aim of the catheter to be maintained.** Organize the equipment in the order that it is to be used during the procedure. This step minimizes fumbling for equipment when the catheter is in the parenchyma. Note the premade markings on the ventricular catheter or mark 4, 5, and 7 cm on the catheter prior to its insertion.

It is strongly encouraged to prepare the drill bit before the skin incision so that no time is wasted preparing the drill with the skull exposed. Choose the appropriate drill bit and insert it into the drill. Adjust the safety stop on the drill bit to the estimated skull thickness. Secure the safety stop on the drill bit firmly with an Allen wrench.

Consider the administration of prophylactic intravenous broad-spectrum antibiotics immediately prior to the procedure. The usual infecting organisms are *Staphylococcus epidermidis* and *Staphylococcus aureus*. Appropriate antibiotic coverage includes third-generation cephalosporins and penicillinase-resistant penicillins.

FIGURE 147-5. Placement of a ventriculostomy catheter. **A.** Insertion of the ventricular catheter. **B.** The catheter is tunneled and the skin closed.

TECHNIQUE

Infiltrate Kocher's point with 3 to 5 mL of lidocaine with epinephrine. Make the incision over Kocher's point marked on the skull. The size of the incision varies by institution. Little more than a stab incision is necessary to complete the procedure. A larger incision of 1 to 2 cm may be useful to visualize the trajectory of the catheter perpendicular to the skull, especially if a large amount of local anesthetic was used. Carry the incision from the skin surface down to and through the periosteum of the skull. Tie off or cauterize any bleeding vessels. Insert the self-retaining retractor into the incision to provide adequate exposure. It is a poor use of time to achieve absolute hemostasis while a patient is decompensating and awaiting the placement of the ventricular catheter. It may be useful to scrape the periosteum off the exterior surface of the skull to avoid skiving of the drill on the skull during drilling.

Aside from placement of the catheter, drilling the skull is one of the highest risk steps in the procedure. Carefully and slowly drill through the outer and inner tables of the skull. **Take care not to penetrate the dura. Do not apply too much force against the drill to prevent plunging the drill bit into the brain.** It is important to develop a tactile feedback as the drill passes through different layers of skull. If there is an anatomy lab or a cadaver dissection available, the best practice is to make multiple passes through the skull on a cadaver model. Drilling has three stages with its own tactile feedback. The bone is dense and tough as the drill passes through outer table. The drill may catch on the skull. The cancellous bone is more easily passed once through the outer table. The drill should not catch until it approaches the inner table. Rotate the drill using the hand crank while slightly pulling back on the drill away from the brain. The threads of the drill will pull it through the inner table. **Stop drilling when a loss of resistance is felt.** Flush the hole with warm sterile saline to remove any debris. Carefully make an opening in the dura (i.e., a controlled durotomy) with an 18 gauge needle or a #11 scalpel blade.

Place the catheter. Placement of the catheter can be associated with trauma to the brain, especially if an incorrect trajectory is used. An incorrectly placed catheter may easily penetrate vital structures such as the thalamus or the prepontine cistern and lead to hematomas. A few basic guidelines should be followed before insertion to avoid such complications. Aim the catheter in two planes. In the

medial-to-lateral plane, aim the catheter to a line through the medial canthus of the ipsilateral eye. In the anterior-to-posterior plane, aim the catheter to a line through the ipsilateral tragus (**Figure 147-5A**). These trajectory lines may be drawn before creation of the sterile field. The final trajectory of the catheter should be perpendicular to the skull.

A simple ventricular catheter or a fiberoptic catheter with a screw-in mechanism should be available. Apply gentle pressure while inserting the catheter into the brain matter and aiming for the medial canthus of the ipsilateral eye (**Figure 147-5A**). A loss of resistance or a "give" will often be felt as the catheter enters the ventricle. There should be a return of CSF at a depth of 4 to 5 cm of catheter penetration. Withdraw the stylet and advance the catheter 1 cm farther. **Do not insert the catheter more than 7 cm deep.** If no CSF is obtained, withdraw the catheter and reinsert it while aiming slightly more medially and posteriorly, as the position of the ventricles may be distorted by the underlying pathologic process. Attach the pressure transducer to measure ICP.

If CSF is not obtained after the third pass, it is important to stop. Leave the catheter in place and obtain a head CT because multiple continuous passes may increase the risk of hematoma formation.²¹ Reposition the catheter to obtain ventricular placement if the head CT shows an obvious correction that could be made to access the ventricle.²² If CSF is still not obtained, take the catheter out and possibly place a pressure monitor or other monitoring device that does not require precise ventricular placement.

ALTERNATIVE TECHNIQUES

The gathering of equipment, making the burr hole, and the insertion of the ventriculostomy catheter can take significant time and experience. The required equipment may not be readily available. An easier, quicker, and simpler technique is to perform a transorbital decompression.^{23,24} This technique is adapted from the frontal lobotomy procedure which was developed in the 1930s. Clean and prep the skin of the eyelids and periorbital area. Moisten sterile gauze with sterile saline. Instruct an assistant to grasp the upper eyelid with a piece of saline-moistened gauze. Instruct the assistant to retract the upper eyelid outward then upward and maintain this position (**Figure 147-6A**). Grasp a piece of saline-moistened gauze in the nondominant hand. Apply this to the sclera at the 12 o'clock

FIGURE 147-6. Transorbital ventricular decompression. **A.** The upper eyelid is retracted and the globe is displaced downward. **B.** Insertion of the needle.

position and displace the globe downward (**Figures 147-6A and 147-6B**). **Do not place the gauze on the cornea as this can cause a significant corneal abrasion.** Apply an 18 gauge, 1.5 to 2.5 inch angiocatheter or spinal needle on a syringe. Insert the needle through the orbital roof, 1 cm posterior to the superciliary arch (**Figure 147-6B**). Aim the needle toward the coronal suture at the midline or vertex of the skull. Advance the needle approximately 3 cm so that its tip enters the anterior horn of the lateral ventricle. Gently aspirate after the needle is inserted to a depth of 3 cm and CSF is aspirated. If using an angiocatheter, the soft plastic catheter can be secured to the orbital roof with a suture and the ICP monitored through the pressure transducer.

A relatively new three-dimensional ultrasound phased array transducer has been developed for burr holes.²⁵ It is 4 to 10 mHz in power. The transducer visualizes the ventricles to increase the EVD placement on the first pass.

AFTERCARE

It is desirable to tunnel the drainage tubing posteromedially subcutaneously for several centimeters to reduce the risk of infection (**Figure 147-5B**).^{2,26} Suture the ventricular catheter and tubing to the skin so that it remains in place (**Figure 147-5B**). Close the skin around the ventricular catheter with 3-0 suture using a figure-of-eight technique (or a running suture if a larger incision was made). Secure the catheter to the skin using a simple drain stitch. If a pressure transducer is being used, obtain a measurement prior to allowing any quantity of CSF to drain. Attach the sterile fluid collection system. If a simple drainage bag is being used, ensure that it is kept at the level of the ventricle to avoid overdrainage. **Frequently recheck and document the patient's neurologic status.** It is useful to send a baseline sample of CSF for culture, cell count, chemistry, and cytology (if applicable) after ventriculostomy placement.

PEDIATRIC CONSIDERATIONS

Young children have an open anterior fontanelle. This large area devoid of bone is ideal for the introduction of a needle to drain CSF from the ventricular system. This procedure may be required in cases

of acute patient decompensation due to an acute nonobstructive hydrocephalus (e.g., meningitis), an acute obstructive hydrocephalus (e.g., brain abscess, brain tumor, epidural hematoma, intracranial hemorrhage, or subdural hematoma), or the acute decompensation of a chronic hydrocephalus (e.g., aqueductal stenosis, posterior fossa tumors, or other congenital malformations).¹²

The ventriculostomy procedure in a young child is similar to that in an older child, adolescent, and adult with a few exceptions. A burr hole is not required as the anterior fontanelle allows an easy access point. Use an 18 or 20 gauge, 1.5 inch long angiocatheter instead of the spinal needle. The procedure is similar to inserting an intravenous catheter. Insert the angiocatheter perpendicular to the skin and at the most lateral aspect of the anterior fontanelle or the coronal suture to avoid the midline sagittal sinus. Stop advancing the angiocatheter when CSF flows from the hub of the needle. Slightly advance the plastic catheter while withdrawing the needle. Apply the pressure transducer to the hub of the catheter to measure ICP. Remove enough CSF to decrease the ICP to an appropriate level or until the signs and symptoms of herniation are reversed.^{26,27} Remove the catheter or secure it to the scalp with suture. The secured catheter can be capped or left attached to the transducer to continue to monitor ICP.

COMPLICATIONS

The most common complication of placement of an emergent ventriculostomy is a CSF infection.^{28,29} The risk of infection increases the longer the drain is left in place. Infections are rare for catheters in place for fewer than 4 days. Tunneling the drainage tubing, adhering to strict aseptic technique, and administering prophylactic antibiotics can reduce the incidence of infection.^{28,30} Antibiotic-coated catheters tend to decrease the rates of infection.³¹

Ventricular puncture can result in an acute bleed in the subdural, intraparenchymal, or ventricular spaces. This can occur from direct trauma to the vascular system or excessive CSF drainage that shrinks the brain and tears the bridging vessels to the subdural space. It is estimated that the risk of hemorrhage associated with a ventriculostomy is 5.7%, with 1% of ventriculostomy patients having a clinically significant hemorrhage.³² **An emergent head CT is indicated if the patient's condition deteriorates further after ventriculostomy**

placement. Patients should always be tested for normal blood clotting function prior to performing a ventriculostomy.

The most feared complication of this procedure is plunging with the drill bit uncontrollably into the brain substance. This procedure should not be performed by those unfamiliar with and untrained in the technique. Apply the minimal amount of pressure to the drill so that the bit penetrates the bone. **Never use a hand twist drill without the safety stop.**

SUMMARY

Patients with traumatic brain injury, acute nontraumatic intracranial hemorrhage, or acute or chronic hydrocephalus from infectious and noninfectious etiologies who present with a rapidly deteriorating neurologic exam may have elevated ICP and/or be in the process of brain herniation. There are several tools in addition to emergent ventriculostomy placement that can temporarily stabilize the patient's changing neurologic status. These include intubation, sedation, hyperventilation, osmotic diuresis, maintenance of cerebral perfusion pressure, dexamethasone administration, and barbiturate coma. Although the ultimate goal is to treat the primary pathologic condition, this chapter was designed to describe the use of CSF drainage via a ventriculostomy and its use in the context of the other methods commonly used to reverse the life-threatening complications of an acutely increasing ICP.

Ventricular Shunt Evaluation and Aspiration

Daniel W. Weingrow and Jacob F. Lentz

INTRODUCTION

Pediatric and adult patients with ventricular shunts frequently seek medical attention in the Emergency Department (ED) with complaints that may or may not be caused by a malfunction and/or infection of these indwelling devices.¹⁻³ Patients with shunts may present with clinical entities as benign as a viral upper respiratory infection or with a life-threatening condition such as hydrocephalus. The wide range of possibilities is a challenge to the Emergency Physician's (EP's) diligence and clinical acumen. The challenge for the EP is to determine if the shunt system is functioning properly and if it is a direct cause of the patient's acute problem. This chapter will discuss the complications of ventricular shunt complications and includes tapping the shunt reservoir in the appropriate circumstance.

Ventricular shunts are lifesaving devices that are particularly prone to complications.⁴ Complications of shunts typically occur soon after placement or revision.^{1,5,6} Approximately 30% of patients who undergo a shunt revision present to the ED shortly after discharge. Children who had shunts placed as infants will require two shunt revisions secondary to obstruction within their first 10 years.⁷ The overall shunt infection rate is 10% to 20%.⁷⁻⁹ Approximately 90% of these infections will present within 3 months of the shunt placement.⁷ Routine injection of the reservoir when placing it may decrease the infection rates.¹⁰ The mortality of shunt-related complications has been estimated to be 4.6%.¹¹ This rate is highly dependent on the type of complication as well as the patient's initial neurologic examination. There is an enormous financial cost associated with ventricular shunts and their complications.¹¹ The use of best practice guidelines may decrease infection rates.¹² All of the above statistics apply to the population with hydrocephalus treated using indwelling ventricular shunt devices. Many of the complications discussed in this chapter may be greatly reduced in the future with the development of neuroendoscopic techniques.¹³ Patients will continue to present frequently to the ED with a variety of problems related to their ventricular shunts. **Unless stated otherwise, the reader should assume that reference is being made to the more common ventriculoperitoneal (V-P) shunt device.**

Undershunting is the most common complication and can result from obstruction, malfunction, or breakage of the device.¹⁴ The next most common category of shunt complication is infection despite being impregnated with an antimicrobial coating. Overshunting is the next most common complication. It may be associated with overshunting syndrome which may be associated with a subdural hematoma, hygroma, and slit ventricle syndrome.

Seizures tend to occur at a high rate after shunt placement. There is controversy as to whether shunt placement is the cause of the seizure or whether seizure activity is actually related to other associated conditions.¹⁵ Patients may have problems related to the distal catheter (e.g., peritoneal hernia for abdominal shunts or endocarditis for atrial shunts).¹⁶ There are other unique complications related to ventriculoatrial (V-A) and ventriculopleural shunt systems that will be discussed separately. There are also complications unique to infancy and childhood (e.g., cranial deformities) that are not managed in the ED.

The patient's significant other or caretaker will usually be familiar with the patient's baseline behavior and the signs and symptoms associated with previous shunt malfunctions.¹⁷ **They represent important sources of collateral information when taking a history.** Neurosurgeons are adept at the evaluation of the ventricular shunts and are a critical resource when a shunt requires revision. **The EP bears the responsibility to recognize a shunt malfunction and other acute diseases that may masquerade as a shunt malfunction. It is in the best interest of patient care that the EP work with patients, families, and Neurosurgeons to achieve the optimal management.**

ANATOMY AND PATHOPHYSIOLOGY

Hydrocephalus is defined by an excessive quantity of cerebrospinal fluid (CSF) and is the condition most frequently associated with the initial need for a ventricular shunt or a shunt revision due to the malfunction of a preexisting shunt. An increase in the volume of CSF can overwhelm the nervous system's compensatory mechanisms and lead to an increased intracranial pressure (ICP). This in turn can lead to problems with cerebral perfusion and central nervous system (CNS) herniation. Obstructive hydrocephalus can cause dilation of the temporal tips of the lateral ventricles, produce compression of the uncus of the temporal lobe against

the brainstem, and lead to herniation. Nonobstructive hydrocephalus can cause pressure on the cerebellar tonsils leading to brain herniation.¹⁸ Increased ICP due to hydrocephalus can be temporized with acetazolamide therapy and ultimately managed surgically by shunt placement.¹⁹

Hydrocephalus is usually due to decreased CSF absorption. It may rarely be caused by increased production (e.g., a choroid plexus papilloma) or because of cerebral atrophy (e.g., hydrocephalus ex vacuo). Hydrocephalus ex vacuo is a radiographic diagnosis that does not require surgical intervention. **There are two main subdivisions among patients with decreased CSF reabsorption, noncommunicating hydrocephalus, and communicating hydrocephalus.** Patients have an obstruction proximal to the arachnoid granulations preventing the normal flow of CSF in noncommunicating hydrocephalus. Patients have unobstructed flow of CSF between the choroid plexus of the ventricular system and the spinal cord but suffer from diminished reabsorption at the arachnoid granulations in communicating or nonobstructive hydrocephalus. This most frequently occurs in patients who have had a hemorrhage or infectious process that resulted in particulate matter interfering with the normal reabsorption of CSF.

Normal pressure hydrocephalus features the radiographic appearance of hydrocephalus with dilated ventricles along with the clinical triad of ataxia, urinary incontinence, and dementia. Normal pressure hydrocephalus is most common in the elderly population. It is, as the name suggests, associated with a normal ICP. The patient usually accumulates CSF due to decreased absorption.

Once the diagnosis of hydrocephalus is made, the Neurosurgeon will be responsible for treating the primary causes (e.g., tumor, bleed, congenital abnormality) as well as placing an indwelling ventricular shunt. The components of a standard shunt system include a ventricular catheter, a one-way valve, and distal tubing that enters the cavity into which the fluid is being shunted (**Figure 148-1**). It is a standard practice to enter the right lateral ventricle through a burr hole in the skull. The proximal catheter is then situated in the right lateral ventricle. It has numerous openings to prevent the choroid plexus from blocking the catheter outflow from the ventricles (**Figure 148-2**). The valve system is placed subcutaneously along the right temporoparietal region. The distal catheter is tunneled subcutaneously along the skull, lateral neck, anterolateral chest wall, and finally into the peritoneal space just superior or lateral to the umbilicus (**Figure 148-3**). The shunt system may occasionally be found on the left side in some patients.

There are two main types and many kinds of valve systems (**Figure 148-4**). The differential pressure valve allows the Neurosurgeon to select a low-, medium-, or high-pressure system. The CSF will flow out of the ventricle through the one-way system when the CSF pressure or CSF flow rate builds to a specified level. They are

FIGURE 148-1. The components of a ventricular shunt.

FIGURE 148-2. The intraventricular catheter with holes to prevent the choroid plexus from blocking it.

adjusted with magnetic tools. A variable resistance constant flow valve keeps CSF rates constant and provides a more physiologic system by varying the resistance in the valve as the individual changes position. Some of these valve systems are palpable on physical examination but do not allow access to the CSF for aspiration. A single or double bubble reservoir (i.e., two bubbles in tandem) for the draining of CSF is a common addition to the standard shunt system (**Figure 148-5**). The reservoir can be inserted anywhere in the system. It is most frequently adjacent to the valve mechanism on the lateral aspect of the skull (**Figure 148-3**).

FIGURE 148-3. The anatomic pathway of a ventriculoperitoneal shunt.

FIGURE 148-4. Examples of different shunt valves. Flow is in the direction of left to right.

The distal catheter has a wire spring embedded in the length of its silicone tubing in order to decrease kinking. The distal tip has numerous openings to prevent blockage. A small incision into the peritoneal cavity allows the distal catheter tubing to exit the subcutaneous tissue and enter the peritoneum. A generous portion of tubing is left free floating inside the peritoneal cavity. This extra tubing allows for the distal end to lengthen as the patient grows and lends further stability to its place within the abdominal cavity. The proximal and distal catheters are impregnated with radiopaque markings to allow verification of the catheter position on radiographs.²⁰

There are many types of configurations of the distal catheter placement. The distal tubing in ventriculoatrial and ventriculopleural shunt systems will terminate in the right atria and right

FIGURE 148-5. Example of a double bubble system.

pleural cavity, respectively. These configurations are not used frequently but it is important to be aware of them. Ventriculoperitoneal shunts have been the preferred modality since the 1960s for most types of hydrocephalus due to their lower complication rate.^{21,22} The EP may come across a patient with a lumboperitoneal shunt that avoids any direct surgical invasion of the brain.²³ The proximal catheter is placed in the lumbar subarachnoid space, the valve and reservoir system are above the iliac crest, and the distal tubing is tunneled subcutaneously in the abdominal wall ending into the abdominal cavity.

A patient with a ventricular shunt is subject to a host of complications from mechanical malfunctions that may occur anywhere in the path of the shunt system.²³ **As with any indwelling medical device there is a risk of infection.** The remainder of this chapter will guide the EP through the process of identifying the various types of shunt problems.

SIGNS AND SYMPTOMS

The clinical presentation of hydrocephalus varies with its severity, rate of progression, and age of the patient. Preverbal pediatric patients with open fontanelles typically have a nonspecific examination. Further collateral information from caretakers is usually necessary to make the diagnosis. Experienced caretakers are accurate in diagnosing shunt malfunction.²⁴ **It is crucial that the EP rely upon collateral information to distinguish shunt malfunction from other acute or nonacute disease entities.** Isolated bradycardia without hypertension is common in children with a shunt malfunction.²⁵

Pediatric patients with a recent ventricular shunt insertion who have nausea and vomiting, irritability, decreased level of consciousness, and a bulging fontanelle are predictive of a shunt malfunction.²⁶ Only decreased level of consciousness and loss of developmental milestones were found to be significant predictive factors in patients with presentations late after shunt insertion.²⁶ Lethargy and shunt site swelling were signs of shunt malfunction in the pediatric population.²⁷

Cranial nerve palsies (e.g., supranuclear upward gaze palsy or Parinaud's syndrome [i.e., sunset eyes or the setting sun sign]) can result from compression of the mesencephalic tectum by a dilated suprapineal recess in patients with more severe hydrocephalus.^{28,29} This can give the patient a "scared" or surprised appearance and cause the patient to extend their neck to compensate. The sixth cranial nerve's long intracranial course leaves it susceptible to compression which can manifest as unilateral or bilateral palsies.³⁰

Elevated ICP can manifest as an engorgement of the scalp veins due to reversal of flow from the intracerebral sinuses.³¹ This may result in a "puffy eyes" appearance, the subtlety of which may escape the EP who is unfamiliar with the patient's normal appearance.³² Papilledema is seen in only 2% of patients with shunt malfunction.³³

Symptoms of shunt malfunction are similar to increased ICP in other disease entities in patients who are verbal with closed sutures.³⁴ They may describe headaches that are classically worse in the morning after awakening from sleep due to relative hypoventilation during sleep which dilates the cerebral veins and the head being at the level of the heart. They may exhibit ataxia and other movement disorders (e.g., hyperreflexia and spasticity that involves the legs greater than the arms).³⁵ Nausea and vomiting may be present due to increasing pressure on the vagal nucleus of the area postrema (i.e., the "vomiting center").³⁶ Patients will display diminishing levels of responsiveness, coma, and an associated Cushing reflex (i.e., bradycardia and hypertension) as ICP continues to rise and prior to the terminal event of herniation.³⁰

Examine the shunt from the site of the burr hole to its insertion cavity. Much of the shunt is palpable. Begin at the burr hole on the scalp. Examine the surrounding scalp carefully for any boggy (i.e., indicating that CSF may have extravasated from the system), erythema, tenderness, or warmth. Examine the suture lines. A shunt reservoir may be palpated under the scalp. It should typically feel like a fluid-filled bubble. Gently compress the bubble to assess if there is brisk refilling of the CSF. Quick filling of the reservoir is an indication that the proximal portion of the system may be patent.^{37,38} **This is by no means a perfect test.**^{37,38} **Resistance to compression indicates a distal shunt malfunction. Avoid pumping the reservoir repeatedly.**

A double bubble reservoir system may be palpated. Compress the proximal reservoir to empty it and fill the distal reservoir. Compress the distal reservoir while still compressing the proximal reservoir. **Any resistance to compression of the distal reservoir indicates a distal malfunction with the shunt system.** Release the proximal reservoir while still compressing the distal reservoir. It should refill very quickly. **A delay in filling of the proximal reservoir indicates a proximal malfunction.**

Continue to palpate the temporal region of the scalp and the neck for any gaps in the system that could indicate a disconnection. The individual components of the shunt system are commonly joined by small connectors that can dislodge from one another. Continue to palpate the tubing along the neck and chest until reaching the abdomen and note any gaps. It is common to fracture the tubing in the area over the clavicle and lower ribs. Perform a thorough abdominal examination.

The distal end of the shunt may not function for several reasons. The tip may have withdrawn out of the peritoneal cavity and into the preperitoneal fat or subcutaneous tissue. This may have occurred because the patient had grown and used up the extra length of catheter that was originally left in the peritoneal cavity. The distal tip can migrate and cause a bowel perforation with or without resultant peritonitis, bowel obstruction, hernias, pleural effusions, and a hydrocele.^{20,39}

Intraperitoneal infections may cause loculations around the catheter tip and form a pseudocyst.^{40,41} It is important to note that these patients may not have any signs of a systemic infection. Additional causes of distal catheter obstruction include kinking of the intraabdominal tubing, debris collection around the tube openings, compression secondary to pregnancy, or other processes that increase the intraabdominal pressure.

Unexplained fever should prompt an evaluation of the distal catheter as a possible nidus of infection in patients with ventriculoatrial shunts.⁴² A new murmur, skin findings consistent with endocarditis, or unexplained end-organ dysfunction should raise the possibility of bacterial seeding from the distal port.⁴³

INDICATIONS

The EP is obliged to assess the patency, placement, and integrity of the shunt system when a patient presents with any symptoms even remotely related to hydrocephalus. The presence of systemic signs (e.g., fever, tachycardia, or hypotension) or local signs of infection (e.g., warmth, tenderness, boggy, or redness along the shunt tract) is a reason to consider aspirating CSF from the system. This is not to say that every child with an upper respiratory infection requires that the shunt be tapped.³ It is not uncommon to have overlapping findings in that an infection may obstruct the system and therefore require both mechanical and infectious complications to be addressed. **The withdrawal of CSF from the shunt can be lifesaving and sustain the patient who is herniating, in extremis, or deteriorating neurologically until a Neurosurgeon can repair the shunt.**

CONTRAINDICATIONS

There are no contraindications to performing a thorough physical examination of the shunt system, obtaining a head computed tomography (CT), and obtaining plain radiographs to assess its integrity. There is some controversy that surrounds the tapping of a shunt by personnel other than a Neurosurgeon.⁴⁴⁻⁴⁶ **It is possible to disrupt the pressure and valve mechanism by the manipulation of the needle that is required to perform the tap. The reservoir may develop a leak if the correct technique is not employed or if the shunt is tapped too frequently.** There is the risk that bacteria will be introduced into the system. Many patients have had multiple complications related to both a primary disease and the shunt, with some already having undergone a number of shunt revisions. **It is prudent to assume a conservative approach with each of these patients and consult a Neurosurgeon prior to tapping the shunt.**

SHUNT ASSESSMENT THROUGH IMAGING

The history and physical are critical in determining if a patient's symptoms are due to shunt malfunction or an alternate diagnosis. **No single collection of signs or symptoms is sensitive in ruling in or out ventricular shunt malfunction.**^{26,27,38} An EP's judgment along with the patient's and caretakers' assessment of symptoms can obviate the need for advanced imaging if the presenting complaint can confidently be attributed to a cause other than a malfunctioning shunt.¹⁷ Imaging of the shunt system and the brain may be required in cases where there is concern for shunt malfunction but clinical uncertainty remains. The EP must use clinical judgment to balance the risk of a shunt malfunction with the cost and radiation associated with advanced imaging.

Both CT and magnetic resonance imaging (MRI) can aid in visualizing the ventricular shunt, characterize and grade the severity of hydrocephalus, and demonstrate secondary signs of increased ICP.⁴⁷ **It can be difficult to determine if there is a change in the ventricular system because preexisting congenital or chronic abnormalities can give the ventricles an abnormal appearance at baseline. The best approach is a comparison to a previous scan.**⁴⁸

The EP should not feel completely reassured by a scan demonstrating ventricles that are "normal" or "unchanged." Patients with a shunt malfunction may not have radiographic findings supporting the diagnosis.^{48,49} There are multiple explanations for this finding. Patients with small ventricles may have noncompliant pressure volume curves requiring extremely high ICPs for significant changes in ventricular size. Small ventricles may be seen in overshunting where the CSF is draining too vigorously. This results in slit ventricle syndrome or intracranial hypotension in which the symptoms are similar to a spinal headache.⁵⁰ **It is important to carefully examine the CT scan for any subdural hematomas or hygromas that can result from the brain shrinking away from the dura and tearing bridging veins from a siphoning effect of over-drainage of CSF.**⁵¹

Scans of patients with both obstructive and nonobstructive hydrocephalus can have a similar appearance to those patients with hydrocephalus ex vacuo due to loss of brain tissue. This can complicate distinguishing normal pressure hydrocephalus from cerebral atrophy in patients with dementia. Two main measurements are used to distinguish these entities. The first is a size greater than 2 mm of the temporal horns of the lateral ventricles when the sylvian and interhemispheric fissures are not visible on the CT or MRI image.⁵² A bilateral frontal horn width greater than half the width of the internal diameter of the skull at the same level is suggestive of hydrocephalus (Figure 148-6).⁵² In pediatric patients, a ratio of

FIGURE 148-6. Head CT of a patient with hydrocephalus. **A.** The ventricles are enlarged with effacement. **B.** Pronounced temporal horns.

the frontal horns of the lateral ventricles to the maximal biparietal diameter as measured in the same slice greater than 0.3 suggests hydrocephalus.⁵³

MRI and CT scans can show signs of increased ICP beyond simple hydrocephalus. These include impending herniation wherein the brain appears to be under increased pressure with a loss of sulcal markings, a loss of differentiation between the gray and white matter, and/or an inability to visualize the fourth ventricle. **Herniation is characterized by compression of the basilar cisterns due to compression at the tentorial notch.**¹⁸

A MRI scan does not yet have the same ubiquitous availability to most EPs. It can give similar information to a CT scan when evaluating hydrocephalus.⁵⁴ An MRI has the added benefit of not exposing the patient to ionizing radiation.^{55,56} The exposure to ionizing radiation has been implicated as a disproportionate risk factor for malignancy in pediatric patients receiving advanced imaging.⁵⁷ Pediatric patients have incompletely ossified calvaria which leads to increased radiation penetration of the brain. Most patients with ventricular shunts undergo many CT scans in their lifetimes due to malfunction, revision, periodic observation, and maintenance.⁵⁸⁻⁶⁰ Limited CT scans of four slices instead of whole brain CT can be used if MRI is unavailable.⁶¹ **The EP should coordinate management with the consulting Neurosurgeon to avoid unnecessary radiation from repetitive scans.**

A protocol was developed for the MRI scanning of pediatric patients with a suspected shunt malfunction.^{58,62} The single-shot fast-spin echo MRI has a short scan time.^{47,55,63-65} There were concerns of movement artifacts in obtaining MRI sequences in children. This is eliminated with a single axial T2 diffusion-weighted sequence in as little as 8 seconds which obviates the need for sedation.⁶⁶ The MRI does have the limitations of identifying bleeds and venous sinus thrombosis.⁶⁵ **Programmable ventricular shunts must be evaluated by a Neurosurgeon after an MRI. Programmable shunt valves tolerate up to a 3 Tesla (T) MRI without permanent damage, but the pressure setting may be altered and should be rechecked after having an MRI for any reason.**³⁰ There are now MRI-resistant programmable valves (e.g., Codman, Raynham, MA, and Medtronic, Minneapolis, MN).

A shunt series of plain radiographs can reveal any mechanical kinks, breaks, fluid collections, or disconnections along the shunt tubing. Shunt materials are impregnated with radiopaque substances and markings which allow the entire device to be visualized on plain radiographs. The threshold to obtain a plain film shunt series should be very low if an EP has the slightest suspicion of a shunt malfunction or infection.⁶⁷ **A shunt series consists of anteroposterior and lateral plain radiographs of the skull, neck, chest, and abdomen.**⁶⁴ These films are useful for assessing shunt positioning and the integrity of the connections within the system.⁶⁸ **Always review the lateral abdominal films as it is impossible to determine if the shunt tubing lies within the peritoneal cavity without it.** Inspect the entire path of the shunt system and note placement of the catheter inside the ventricle, the integrity of the connections around the valve and/or the reservoir, the identification of the distal catheter within the peritoneal cavity, and any kinks or breaks in the system. Examine the chest radiographs closely for any pleural effusion or pneumothorax from migration of the distal end of the tubing.³⁹

Radionuclide scanning with technetium along with manometry is highly sensitive for shunt malfunctions when a high suspicion of shunt malfunction exists but CT or MRI imaging is unremarkable. This scanning technique is invasive and involves radiation exposure.⁶⁹ The EP should be aware of these highly sensitive tests. It should be left to the discretion of the consulting Neurosurgeon to make the determination for radionuclide scans.

SHUNT ASPIRATION

The indications for tapping a shunt reservoir in the ED include the following: to obtain a CSF specimen if there is a clinical concern of a shunt infection; to evaluate shunt function if there is suspected obstruction; and as a temporizing measure in a potentially distally occluded shunt when the patient is in extremis, deteriorating neurologically, or has signs of herniation on CT scan.⁷⁰ This can temporarily restore cerebral perfusion and sustain the patient until a Neurosurgeon can repair the shunt. **It is recommended that a Neurosurgeon be consulted and given the first option to perform the procedure.** The Neurosurgeon may have already manipulated the hardware multiple times and will ultimately be responsible for any shunt revisions and follow-up.

Patients with ventriculoatrial shunts are a particular concern when there are any signs of an infection. The distal catheter sits at the intersection of the right atrium and the superior vena cava. This puts the patient at risk for life threats such as endocarditis and septic emboli. It may be possible to evaluate the majority of shunt malfunctions without tapping the device.⁴⁴

Tapping a ventricular shunt is a quick and simple procedure. Palpate the lateral aspect of the skull for the reservoir. Plain radiographs or bedside ultrasound may be helpful if it is difficult to identify upon palpation.⁷¹ Prepare for the procedure by having the following equipment available: four sterile fluid specimen tubes with tight-fitting tops (those supplied in the standard lumbar puncture kit are ideal), a 23 to 25 gauge butterfly needle, a 5 to 10 mL syringe, a shave-prep set, an antibacterial cleansing preparation (e.g., povidone iodine or chlorhexidine solution), a fenestrated drape, and sterile personal protective equipment. A lumbar puncture tray supplemented with a butterfly needle and attached tubing will provide all the supplies. Consider the application of cerebral regional tissue oxygen (rSO₂) before, during, and after the tap.⁷² It may help in the detection of the malfunction.

Local anesthetic is not required for this procedure. Place the patient in whatever position is mutually comfortable. Shave a small patch of hair overlying the reservoir. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. **This procedure requires strict aseptic technique.** The EP should don full sterile and personal protective equipment at this point. This includes sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Place the drape over the patient's head so that the fenestration overlies the reservoir and prepped skin. Set up a bedside table with a sterile drape and all the supplies.

Insert the needle at approximately 45° from the vertex of the reservoir bubble with the tip pointed toward the center of the reservoir (Figure 148-7). This is where the greatest amount of CSF is located. **Avoid inserting the needle into any of the connections or internal pressure mechanisms that may be at either end of the reservoir.** Allow the CSF to passively drain from the butterfly tubing into sterile tubes.

Spontaneous CSF flow indicates that the proximal portion of the ventricular shunt is not completely occluded. Attach a manometer to the end of the butterfly tubing to measure the opening pressure. Alternatively, hold the length of the butterfly needle tubing upward as the length of a typical tube is approximately 30 cm. Manometry readings indicating that the intraventricular pressure is greater than 20 cmH₂O is a concern for distal obstruction.⁷³ The normal pressure is 10 to 20 cmH₂O in a relaxed lateral recumbent patient with the reservoir facing upward. Attempt to gently aspirate CSF with a 5 mL sterile syringe if there is no spontaneous CSF flow. The proximal (i.e., ventricular) end is likely obstructed if CSF is difficult to aspirate.⁴⁶ Withdraw the needle from the shunt reservoir and apply pressure to tamponade any bleeding.

FIGURE 148-7. Tapping the shunt reservoir. **A.** Artist Illustration. **B.** A shunt and butterfly needle. (Used with permission from reference 6.)

Label the tubes of CSF and have them transported to the laboratory for a cell count and differential, Gram stain, culture (e.g., bacterial, viral, and fungal), and chemistry (e.g., protein and glucose). Obtain a sample of the patient's serum glucose at the same time so as to more accurately determine what level of glucose in the CSF to call abnormal. **A normal level of CSF glucose should not be any lower than 50% to 66% of the serum level.**

Obtain a nuclear medicine scan (i.e., a shunt-o-gram) if CSF cannot be aspirated to determine the proximal patency of the system. A radioactive isotope (e.g., technetium) is injected into the reservoir after manually occluding the distal shunt tubing. The flow, or lack thereof, of the radioactive isotope is then imaged.⁷⁴ This form of imaging can increase the sensitivity for the detection of a shunt malfunction.⁷⁵

A lumbar puncture should never be performed in lieu of tapping the shunt. Obstruction of the shunt system can result in obstructive hydrocephalus. Lumbar puncture in a patient with obstructive hydrocephalus can cause a significant pressure differential and precipitate brain herniation.

CSF ASSESSMENT

The CSF obtained from the shunt is interpreted in the same way as CSF is interpreted from a lumbar puncture. A high white cell count with a large number of polymorphonuclear leukocytes, low glucose, and a high protein level indicates a high likelihood of bacterial infection. The positive Gram stain and culture make the definitive diagnosis.⁷⁵ There is no standard for the number of white cells that definitively indicates an infection. Some patients with indwelling shunts may have a chronically elevated CSF white blood cell count with more lymphocytes or eosinophils than polymorphonuclear leukocytes.⁷⁶ Refer to Chapter 142 for a more detailed discussion regarding the evaluation of CSF. **Antibiotic coverage should be initiated if a shunt is being tapped.** *Staphylococcus epidermidis* causes the vast majority of infections, with *Staphylococcus aureus* and gram-negative bacilli following in frequency.⁷⁷ The current management of shunt-related infections has been reviewed.⁷⁸ Empiric therapy includes vancomycin with either cefotaxime or ceftriaxone for children and vancomycin with rifampin for adults.⁷⁹ Consider additional coverage for methicillin-resistant *S. aureus* if indicated.

COMPLICATIONS

There are a few complications associated with the aspiration of a ventricular shunt. The introduction of bacteria into the reservoir can result in meningitis, peritonitis, brain abscesses, shunt occlusion, or infection anywhere along the course of the shunt tubing.^{80,81}

It is of the utmost importance to maintain strict sterile technique. The needle can damage the reservoir and result in a permanent hole necessitating its removal and replacement.⁸² A misplaced needle can damage the connections or valves of the shunt system.

FUTURE CONSIDERATIONS

The use of bedside ultrasound can be very helpful. It can identify a fluid collection along the subcutaneous tubing as an abscess.⁸³ It can identify an extracranial tubing fracture by visualizing the abrupt ending of the tubing and an associated fluid collection.^{68,84} The benefits of bedside ultrasound are that it can be readily repeated, lacks ionizing radiation, and is quickly available for an unstable patient. Transcranial sonography has some utility in patients with open fontanelles. The majority of studies on the use of transcranial ultrasound have been performed in the Neonatal Intensive Care Unit where germinal matrix intraventricular hemorrhage and subsequent posthemorrhagic hydrocephalus in premature neonates often necessitates surgical intervention.⁸⁵ Serial measurements of the lateral ventricles aid in the therapeutic evaluation of hydrocephalus. The precise reference values are critical, as intervention may be based on ventricular size changes of only a few millimeters.⁸⁶

This research has expanded to include the sonographic estimation of ICP using optic nerve sheath diameter.⁸⁷ There have been reports of bedside ultrasound being used for the evaluation of problems with shunt tubing using spectral Doppler to evaluate presence or absence of flow in a ventricular shunt model.^{88,89} Ultrasound can be used to locate a difficult to palpate shunt reservoir.⁷¹

The ShuntCheckT (NeuroDx Development, Princeton, NJ) is a device that allows the noninvasive detection of CSF flow through a shunt.⁹⁰ The procedure requires placing an ice cube over the shunt. A single patient use and disposable sensor is placed on the skin of the neck overlying the shunt tubing. The sensor is attached to the ShuntCheckT device with a cable. The ShuntCheckT analyzes the temperature readings from the sensor and determines if CSF flow is present or not.

SUMMARY

Patients with indwelling ventricular shunt devices are subject to many complications throughout their lives. These most commonly include obstruction, infection, and malfunction. The EP will see shunt patients of all ages who present with headache, fever, nausea, vomiting, seizures, irritability, or a change in mental status. The challenge is to determine whether or not the patient's complaint is related to the shunt. This chapter discussed some of the common shunt complications and an approach to their diagnosis. A careful history and a skilled physical examination will set the EP on a path toward a good patient outcome. The brain imaging, the plain film shunt series, and the shunt tap will prove most useful. A Neurosurgeon should always be consulted. A conservative approach to the diagnosis, management, and patient disposition is strongly recommended due to the life-threatening nature of shunt complications.

Subdural Hematoma Aspiration in the Infant

Sarah Christian-Kopp

INTRODUCTION

Extra-axial fluid collections are described as fluid collection that are external to the brain parenchyma. These include epidural hematomas, subdural hematomas, and subarachnoid hemorrhages. Intra-axial fluid collections develop within the brain parenchyma. Extra-axial fluid collections in children are classified as symptomatic and asymptomatic. Symptomatic extra-axial fluid collections have been classified as effusions, hematomas, or hygromas. Their appearance on computed tomography (CT) scans and the treatment for each are identical (**Figure 149-1**).¹ CT scan images of symptomatic extra-axial fluid collections usually demonstrate ventricular compression and flattening or obliteration of the cerebral sulci on CT scans (**Figure 149-1**). Asymptomatic or benign subdural fluid collections usually appear as a hypodensity over the frontal lobes with dilation of the cortical sulci, interhemispheric fissure, and Sylvian fissure. The ventricles are usually normal in size or slightly enlarged with no evidence of transepandymal flow.

FIGURE 149-1. CT scan image of a subdural hemorrhage.

Common presenting symptoms of a symptomatic extra-axial fluid collection include a depressed level of consciousness, lethargy, irritability, a large head, seizures, or vomiting. The physical examination may reveal fever, a full fontanel, gaze paresis, hemiparesis, increased tone, lethargy, macrocephaly, and retinal hemorrhages. Markwalder has done an excellent review of the pathophysiology and experimental studies of chronic subdural hematomas.²

Most extra-axial fluid collections result from head trauma, whether due to accidental trauma or nonaccidental trauma (NAT) formerly known as abuse.³ Other causes include the placement of a ventriculoperitoneal shunt and postinfectious bacterial meningitis. The etiology of intracranial hemorrhage and extra-axial fluid collections is quite varied (Table 149-1). Acute and chronic subdural fluid collections are not rare problems during infancy. Males are affected more commonly than females.

TABLE 149-1 The Etiologies for Intracranial and Extra-Axial Fluid Collections

Brain atrophy
Child abuse
Coagulopathy
Hydrocephalus
Infection
Masqueraders
Craniocerebral disproportion
External hydrocephalus in a child with ventriculomegaly and extracerebral fluid
Extracerebral space is enlarged and filled with CSF-like fluid from the head being too large for the enclosed brain
Neoplastic
Metastatic
Primary
Prior surgery
Spontaneous
Trauma
Vascular
Aneurysm
Vascular malformation
Ventriculoperitoneal shunt malfunction

Look for a clear history of injury or trauma in the presence of an acute or chronic subdural hematoma.³ Consider the possible etiology of NAT if a history of an injury is not forthcoming or if the history does not make sense. It is incumbent upon the medical team to rule out abuse. This may require a period of inpatient observation, social services consultation, forensics consultation, a radiographic skeletal survey, a bone scan, and possibly an ophthalmological consultation. The presence of retinal hemorrhages in association with a subdural fluid collection is highly suspicious for NAT.⁴ Admission to the hospital for further observation is warranted if NAT cannot be ruled out. Err on the side of precaution. The presence of congenital anomalies may predispose the child to subdural hematoma formation.⁵ An extra-axial fluid collection alone is not pathognomonic for NAT.

Percutaneous removal of the subdural fluid is useful in diagnosing an active infection and rapidly lowering the intracranial pressure in the symptomatic patient.⁶ Repeated removal of the fluid by percutaneous aspirations has been advocated by some Neurosurgeons for definitive treatment of chronic extra-axial fluid collections.^{7,8} Subdural fluid collections in infants do increase in size, are often bilateral, can be difficult to diagnose, and are most often seen in children under the age of two years. The combination of CT and magnetic resonance imaging (MRI) is usually diagnostic.

ANATOMY AND PATHOPHYSIOLOGY

A subdural aspiration or tap is usually performed by puncturing the anterior fontanel. It can be approached through the coronal suture or the soft cranium. The diamond-shaped anterior fontanel is formed by the junction of the sagittal, coronal, and frontal sutures (Figure 149-2). It measures approximately 4 cm in the anteroposterior plane and 2.5 cm in the transverse plane. The bones of the infant skull are separated by connective tissue bands referred to as sutures. The fontanels are readily palpable at the junctions of the sutures. Six of the fontanels are located at the corners of the two parietal bones. Two of these, the anterior and posterior fontanels, are in the midline.

The anterior fontanel is the largest of the neonatal fontanels and is utilized for percutaneous subdural aspiration. The diamond-shaped anterior fontanel is formed by the junction of the coronal suture and sagittal suture (Figure 149-2). It measures approximately 4 cm in the anteroposterior plane and 2.5 cm in the transverse plane. The posterior fontanel is at the junction of the lambdoid and sagittal sutures. The anterior fontanel has usually closed by 18 months of age but can be patent up to the age of 2 years. The posterior fontanel usually closes by 6 to 8 weeks of age.

The anterior fontanel is readily palpable and bulging in cases of symptomatic extra-axial fluid collections. The lateral extent

FIGURE 149-2. Surface anatomy of the infant skull. The shaded area represents the underlying superior sagittal sinus.

of the anterior fontanel is continuous with the coronal suture (**Figure 149-2**). The anterior fontanel is composed of connective tissue and easily perforated with a spinal needle.⁶ Continued advancement of the needle would then perforate the underlying dura, allowing the tip of the needle to rest within the subdural space. Traversing the dura is usually associated with a definite change in resistance as the subdural space is entered. Successful entry of the tip of the needle into the subdural fluid collection can be confirmed by removal of the stylet and observing spontaneous drainage from the needle hub.

INDICATIONS

A subdural aspiration is performed for diagnostic purposes and for rapid decompression of subdural fluid collections (i.e., acute or chronic).⁶ Perform a subdural aspiration in the young child with a subdural fluid collection and radiographic signs of elevated intracranial pressure, a depressed level of consciousness, and/or a changing level of consciousness if a Neurosurgeon is not available.⁹ A subdural aspiration may be considered in the presence of other clinical signs and symptoms associated with elevated intracranial pressure (i.e., bulging fontanelles, coma, cranial nerve palsies, hemiparesis, hypotonia, irritability, lethargy, posturing, seizures, somnolence, and vomiting that is repeated or intractable). **Aspiration of extra-axial fluid collections can reduce intracranial pressure dramatically.** Subdural aspiration of fluid allows for culture and sensitivity, identification of microorganisms, and aids in the selection of bacterial specific antimicrobial agents if an infectious etiology is the cause of the extra-axial fluid collection.

CONTRAINDICATIONS

The main contraindications to performing a subdural aspiration include absence of the anterior fontanel from premature closure, age of 2 or older, coagulopathy, congenital anomalies of the skull or brain, scalp infections, solid clots that are not liquefied, and thrombocytopenia. **Do not perform this procedure if unfamiliar with the technique and its complications. Consult a Neurosurgeon, if available, prior to performing this procedure.** Repeated aspirations are rarely indicated as blood or fluid reaccumulation often requires the placement of a drain or a surgical procedure.

EQUIPMENT

- Sterile skin prep kit
- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Sterile drapes
- 1% or 2% lidocaine, with or without epinephrine
- 18 to 22 gauge, 1.5 inch spinal needle or angiocatheter
- Tincture of benzoin or Mastisol
- Cotton swab
- Bandage
- Bundling blanket
- Commercially available immobilization device
- Syringe for aspirating fluid
- Sterile specimen containers
- Culture bottles or swabs
- IV extension tubing, optional

FIGURE 149-3. An example of a lumbar puncture kit.

The basic equipment can be found in commercially available pediatric lumbar puncture kits (**Figure 149-3**). The kit may need to be supplemented with personal protective equipment and skin antiseptic.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. It is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Apply full monitoring with a cardiac monitor, end-tidal carbon dioxide monitor, noninvasive blood pressure cuff, and pulse oximetry. Obtain a CT scan of the head to determine the presence of an extra-axial fluid collection, the location and extent of the fluid collection, and the type of fluid (e.g., blood, fluid, or pus), and to rule out the presence of a mass (**Figures 149-1 and 149-4**). A sonographer with bedside ultrasound training for the presence of a subdural hematoma can substitute (**Figures 149-4 and 149-5**).¹⁰ Consider an ultrasound when the patient's condition prevents moving them for a CT or MRI. Obtain a complete blood count (i.e., hematocrit, hemoglobin, and platelet count) and a coagulation profile (i.e., prothrombin time, partial thromboplastin time, and international normalized ratio) to ensure that the patient is not coagulopathic or thrombocytopenic.

FIGURE 149-4. Coronal CT image (left) and corresponding ultrasound image (right) of an acute (thin arrow) on chronic (thick arrow) subdural hemorrhage in a 2-month-old. (Used with permission from reference 13.)

FIGURE 149-5. Sagittal ultrasound image of a subdural hemorrhage (arrow) in a 10-month-old. (Used with permission from reference 13.)

Place the patient supine on a stretcher. The child may need to be restrained to prevent movement during the procedure (Chapter 232). Bundling an infant in a blanket and placing their head close to the edge of the bed facilitates aspiration. An alternative is to use a commercially available immobilization device (e.g., Papoose board). The aid of an assistant to hold the child's body with the head straight and upright is recommended if the child is restless. Some children may require the administration of parenteral sedatives or procedural sedation (Chapter 159).

This procedure requires strict aseptic technique. Shave the frontal and parietal regions of the child's head. Clean any dirt and debris from the scalp. Identify by palpation the anterior fontanel, the coronal suture, and the lateral margin of the coronal suture. Don full sterile and personal protective equipment (i.e., cap, face mask with an eye shield or goggles, sterile gloves, and sterile gown). Apply povidone iodine or chlorhexidine solution to the skin over the entire scalp and allow it to dry. Ensure that the solution is not allowed to drain onto the baby's face or eyes. Apply sterile drapes to leave the frontal and parietal regions of the skull exposed. A local anesthetic agent is usually not required but may be used at the Emergency Physician's discretion. Place a skin wheal using 0.25 to 0.50 mL of 1% or 2% lidocaine or apply a topical lidocaine cream at the site the needle will enter the scalp.

TECHNIQUE

Form a Z-tract by gently sliding the scalp skin laterally (Figure 149-6). Insert a 22 gauge spinal needle perpendicular to the skull into the lateral margin of the anterior fontanel, about 2.5 to 3 cm off the midline (Figure 149-6). Advance the spinal needle beneath the frontal bone until the subdural space is penetrated (Figure 149-7). This is usually within 5 to 8 mm from the skin surface. A loss of resistance is usually appreciated as the dura is penetrated and the subdural

FIGURE 149-6. Subdural fluid aspiration. The needle is inserted at the lateral border of the coronal suture and at 90° to the skull.

space is entered. **Do not advance the needle any further. Securely hold the spinal needle so that it does not move (Figure 149-7).** An alternative is to insert the needle at a 45° angle to the skin surface and tunnel it under the scalp into the subdural space (Figure 149-8). Remove the stylet. Spontaneous drainage is often appreciated. The fluid may appear hemorrhagic. It is not uncommon to drain xanthochromic fluid.

The initial subdural aspiration usually results in spontaneous drainage through the spinal needle. **The spontaneous cessation of flow through the needle suggests that the extracranial and intracranial pressures are equalized, not that the fluid has been completely evacuated.** If the fluid does not spontaneously drain, carefully and gently apply a syringe to the spinal needle and gently aspirate the fluid. **Use minimal negative pressure to just aspirate the fluid collection and prevent pulling the brain or any bridging veins into the needle.** Alternatively, apply digital pressure to the anterior fontanelle to increase the flow through the spinal needle. Intravenous extension tubing may be connected to the spinal needle to allow the subdural fluid to drain away from the patient and directly into the specimen tubes. This is left to the Emergency Physician's preference.

Observe the gradual flattening of the anterior fontanel to determine the endpoint for the procedure.¹¹ Aspirate no more than 25 to 30 mL of subdural fluid during the procedure. Larger volumes up to 80 mL have been safely aspirated.¹² Remove the spinal needle and apply a bandage to the skin puncture site.
